Quaternary ammonium compounds of the type $N(R\ OH)_4$, are produced by the action of alkene oxides on tertiary alkylolamines, if the alkalinity of the mixture is maintained almost at the neutral point at the beginning of the treatment.[148] Hydrogen chloride, formic, acetic, lactic or stearic acids, or mono sodium phosphate have been found suitable for buffering the solution in this manner, but carbon dioxide is not effective. For example, when a soap made from stearic acid and triethanolamine is treated with ethylene oxide, the foaming agent obtained may be converted into tetraethanol ammonium hydroxide by reaction with sodium hydroxide solution. Or, if a solution of the same tri-amine in aqueous sulphuric acid has been treated successively with ethylene oxide and mineral acid, the product will furnish the quaternary compound on addition of barium hydroxide.

The salts of the quaternary alkylolammonium compounds are soluble in 35 per cent sodium hydroxide solution. They include such compositions as tetra-(β-hydroxyethyl)-ammonium hydroxide, acetate, stearate, disodium phosphate, tri-(β-hydroxyethyl)-butyl and diethyl-di(β-hydroxyethyl)-ammonium hydroxide.

USES OF THE ETHANOLAMINES

The ethanolamines and particularly triethanolamine are finding increasing application in the industries. Among the numerous chemical products made from ethylene oxide, these amines must be classed as subsidiary only to the glycol ethers in technical importance.

The ethanolamines, especially the tri- and di- forms, are employed in the removal of carbon dioxide and hydrogen sulphide from gases. The operation is usually carried out in countercurrent operations and sometimes under pressure. The dissolved gases are readily removed from the absorption liquid by heating. Developments in the so-called Girbotol purification system, in which ethanolamines are employed, have been reviewed by Bottoms and Wood.[149] According to Allner,[150] a 50 per cent aqueous solution of triethanolamine is about equal, as regards its performance in carbon dioxide removal, to a 20 per cent potassium carbonate solution. Although the dissolved amine does not tend to deposit crystals, its use necessitates very careful packing of pump glands if leakage is to be avoided. Hirst and Pinkel[150a] state that a 50 per cent aqueous solution of triethanolamine is

less efficient than either a 50 per cent solution of diethanolamine or a 5 per cent solution of tetramine. In ethanolamine solutions for gas purification, Bottoms[151] proposes to include boric acid for inhibiting corrosion of the apparatus. He also points out[151a] that such corrosion of iron or steel and decomposition of the ethanolamine may be prevented by means of vanadium or arsenic compounds, such as sodium arsenite or vanadate. Removal of carbon dioxide by countercurrent scrubbing with triethanolamine bicarbonate solution under pressure, followed by regeneration by heating under reduced pressure, has been described by Allen and Michalske.[152]

Comparisons of absorption of carbon dioxide by aqueous solutions of tri- and monoethanolamines and of diaminopropanol, $(NH_2CH_2)_2CHOH$, have been made by Gregory and Scharmann.[152a] They found that triethanolamine was only about one-half as effective as monoethanolamine or the diamino compound. The heat of absorption of carbon dioxide in both of the two latter substances was high, about 750 B.t.u. per lb. of dioxide, thus necessitating the use of dilute solutions (about 30 per cent) of the absorbents. It was also noted that in all instances the liquids must be kept free of dissolved oxygen otherwise they exert considerable corrosive action on the apparatus employed.

Fife[153] eliminates sulphur compounds from industrial gases by scrubbing with water containing 15-30 per cent of ethanolamines and not less than 1 per cent of a soluble compound of copper, iron, nickel or zinc. The solution is regenerated by aeration followed by addition of unslaked lime. The foaming tendency of such aqueous solutions is said to be suppressed by continuously circulating a portion of the solution through activated carbon. A small proportion of fatty oil may also be added to the solution with advantage. An ethanolamine, such as monoethanolamine, containing 3 per cent of boric acid, has been proposed[154] as a component of absorption liquids for weak gaseous acids, and a solution of triethanolamine is specifically recommended[155] for the removal of hydrogen sulphide from gases. A number of complex bases, including those with at least 2 nitrogen atoms and at least one hydroxyalkyl or hydroxyaryl group, have also been suggested for this purpose.[156] Brachfeld and Smola[157] propose to remove carbon dioxide, but not hydrogen sulphide, from gases by washing with an undiluted difficultly volatile amine, such as ethanolamines and morpholine derivatives. The absorbed gases may be recovered by treatment at raised temperatures with the vapor of a water-insoluble organic solvent, such as benzene, which forms an azeotropic mixture with water.

Govers[158] reports that after distillation of a petroleum fraction (under reduced pressure) in the presence of a gaseous distillant, e.g., sulphur dioxide or carbon dioxide, the latter may be removed from the liquid by treatment with the tri-amine.

In another method,[159] a gaseous mixture containing ammonia and hydrogen

sulphide is first washed with sulphuric acid to form ammonium sulphate. Monoethanolamine in aqueous solution is then utilized for removal of the sulphide. The latter is recovered by heating the solution and is converted into sulphur dioxide and then progressively to sulphuric acid.

SOAPS

The ethanolamines may be employed in the form of their soaps, the aqueous solutions of which have low surface and interfacial tensions and hence exhibit good emulsifying properties. Triethanolamine ȯleate is, perhaps, the most commonly used. On account of its solubility in organic solvents it finds application in dry cleaning.[160] One composition of this type consists of a paste of the soap in an alcohol (e.g., n-propyl) admixed with a hydroxy ether (for example, the butyl ether of ethylene glycol), water and a low-boiling petroleum distillate.[161] Another method of preparing alcohol amine soaps has been described.[161a] It consists of partially sulphonating petroleum oil with sulphuric acid, separating the acid sludge, and admixing the remaining acid oil with triethanolamine.

The use of alkylolamines in the fat, oil and wax industries has been reviewed by Fischer.[162] Triethanolamine soaps have been proposed as constituents of lip-rouge,[163] in cosmetic preparations with glycol derivatives,[164] in products for glazing or finishing textile materials,[165] in the separation of wax from oils,[165a] and in the oil-proofing of porous fibrous material.[166] Hydroxyalkylamines, such as diethanolamine, are recommended as ingredients of an aqueous bath for use in washing and cleansing textiles, cotton and wool.[167] Salts of ethanolamines with oleic, ricinoleic and stearic acids, have been suggested as dispersing and emulsifying agents, soluble oils and antiseptics,[168] and as antiknock ingredients for motor fuels.[169] Naphthenic sulphonic acid salts of the alkylolamines are proposed as auxiliary agents in hydraulic cement.[170]

The products of the reaction ȯf carboxylic acids (particularly of more than 10 carbon atoms) with alkylolamines are proposed by Ellis[171] for increasing the load-bearing capacity of mineral lubricating oils. Addition is made to the extent of about 0.5 per cent or more. Such compounds include both esters and salts of alkylolamines, preferably the trihydroxyamines such as triethanolamine. Beale[172] recommends an alkylolamine salt of a fatty acid as a top cylinder lubricant. It is

added in the proportion of 20 to 200 cc. per gallon of gasoline. The salt may be first dissolved in a mineral oil and added to the fuel or mechanically introduced into the cylinder.

The esters of hydroxyamines with higher carboxylic, sulphonic or sulphocarboxylic acids are suggested as dispersing agents for graphite in lubricant manufacture. The monooleic ester of triethanolamine is typical of the suggested substances.[173] Stable emulsions may be obtained from triethanolamine, oleic acid and kerosene and other mineral oils or sulphonic derivatives of petroleum.[174] The physical characteristics of such emulsions have been studied by Risi and Bernard,[175] who also compared their lubricating properties with those of technical lubricants. Another composition which may be employed as a lubricant comprises hydrogenated mineral oil emulsified with water, employing ethanolamine as the dispersing agent.[176]

The phosphoric acid salts of esterified alkylolamines are utilized by Albrecht[177] as constituents of rust-preventive or coating compositions. Thus, triethanolamine is esterified by heating at 176-250°C. with a higher fatty or resin acid of molecular weight greater than 150, for example, the acids of linseed oil. The resulting ester is then converted into its orthophosphate. The products are soluble in paint and varnish media and have rust-preventing properties when applied to metal surfaces.[178] Small quantities of citric or tartaric acids are added to counteract an "alligatoring" effect in the film.

Shaving compositions are said to be improved by the incorporation of 15-30 per cent (calculated on the soap and other solids present) of a secondary or tertiary phosphate of an organic base, such as triethanolamine. Combinations of mono- or polyhydric alcohol-amines with mineral or organic acids, other than those forming soaps, are proposed by Coustolle[179] as ingredients in cleansing agents for the skin. The proposed acids include hydrochloric, sulphuric, nitric, phosphoric, boric and glycerophosphoric. Dispersing agents advanced by Bertsch[180] consist of the reaction product of aliphatic hydroxyamines and sulphonated high-molecular weight aliphatic alcohols of more than 8 carbon atoms, for example, the triethanolamine salt of the sulphuric acid ester of oleyl alcohol.

Triethanolamine has been suggested as a useful addition to a wide variety of products (some which have been noted) including dentrifices,[181] shaving cream and soap,[182] hair dyes,[183] soldering flux,[184] lime-soap greases,[185] foundry sand-core compositions,[186] aluminum soap to be used with gasoline or benzene for waterproofing fabrics or stone[187] and as a component of a material for the manufacture of gaskets.[188] Other suggested applications of this trialkylolamine are in aniline black printing,[189] in the manufacture of rubber sponge,[190] in the preparation of sizing, proofing, wetting and scouring agents for textiles,[191] in the removal of "catalyst taste" of hydrogenated oils[192] and for refining the oils obtained by separation of oil-water emulsions.[193] A solid wax dispersion, used in the preparation of emulsions for coating citrus fruits,[194] may be made of paraffin and carnauba waxes, cottonseed oil, oleic acid and triethanolamine (10 per cent by weight).

Free alkylolamines may be recovered from extracts or residues obtained in refining oils, fats, waxes and resins.[195] The method recommended consists of distillation with steam under reduced pressure after the addition of basic substances such as alkali soaps or alkali or alkaline-earth oxides to suppress amide formation. The low-boiling fractions contain alkyl- and alkylolamines. Kaladzhal[196] found that the influence of aluminum stearate in lowering the pour point of mineral lubricating oils is enhanced by the addition of small proportions of triethanolamine. An anti-rusting composition for preventing corrosion in stored engines may be prepared[197] from 5 to 6 per cent of triethanolamine, 10 per cent aluminum stearate, 10 to 12 per cent butanol and lard oil.

Triethanolamine (and similar bases) have been recommended for use in the preservation and stabilization of a number of organic chemicals. Thus, glycol ethers which tend to deteriorate on storage are preserved against discoloration by the addition of less than 1 per cent, generally about 0.1 per cent by volume, of the base.[198] Aromatic alcohols, such as benzyl alcohol, prepared from the corresponding halide by hydrolysis, are said[199] to be stabilized by heating with about 3 per cent of a high-boiling base, such as triethanolamine, at above 100°C., followed by distillation. The addition of not more than 0.02 per cent of an ethanolamine to petroleum distillates, such as gasolines or kerosenes, is purported[200] to render them stable as regards color, gum formation and odor.

Alkylolamines are suggested[201] as agents for increasing the heat resistance and for diminishing any corrosive action of cellulose esters and ethers. They may also be applied in the refining of the esters.[202] Neutral solutions of inorganic salts of such bases, particularly of triethanolamine, are employed to effect fireproofing of textile materials without affecting the pliability and smoothness necessary for subsequent processing operations.[203] Triethanolamine lactate is proposed[204] as an agent for the treatment of filaments, films and fabrics. Rayon is said to be protected from the injurious action of oxidation products of drying oils by inclusion, in the dressing, of a water-soluble base such as triethanolamine.[205] The ethanolamines and related compounds have found application in such varied uses as the concentration of aliphatic acids,[206] the reclaiming of oils containing carbon,[207] the inhibition of corrosion in automobile radiators,[207a] and the manufacture of esters of leuco-compounds of vat dyes.[208]

The sulphuric esters of mono- and diethanolamine, and also of similar primary and secondary alkylolamines, may be halogenated to yield compounds capable of liberating free halogen and thus are reported to be useful as bleaching agents.[209] The condensation of ester-type waxes with primary or secondary nitrogen bases, such as ethanolamine, is said[210] to furnish products of value as polishes, textile finishes and in rubber compounding. Salts of ethanolamines with aromatic, aromatic-aliphatic or heterocyclic sulphonic or carboxylic acids, containing iodine substituted in the ring, have been described.[211]

A mixture of Carbitol and an organic acid salt of triethanolamine is advocated as a hydraulic pressure-transmitting fluid.[212] Trialkylolamine may be added to solid carbon dioxide to improve its physical characteristics.[213] Greer[214] proposes to employ, *inter alia*, triethanolamine as a dehydrating medium for drying diethyl ether to less than 0.6 per cent of water, the ether being collected by distillation.

Triethanolamine hydroxyabietate may be produced by treating a gasoline solution of wood rosin with triethanolamine.[215] The salt is soluble in alcohol but is hydrolyzed by hot water. Other alkylolamines react similarly with rosin, and it is believed that such treatment may be useful in the refining of rosin.

DIOXANE AND ITS DERIVATIVES

Dioxane and its homologues may be prepared by the dehydration of the corresponding 1,2-glycols under the influence of sulphuric acid. Steimmig and Hambsch[216] have described a continuous process for the preparation of such compounds from a mixture of homologous 1,2-glycols by heating with concentrated sulphuric acid at the boiling point of the acid liquor. The products are allowed to distil off, and a corresponding amount of glycol is continuously added.

Another mode of synthesis of dioxane involves the catalytic dimerization of ethylene oxide. Passage of ethylene oxide at about 120°C. over a solid alkali bisulphate catalyst is said[217] to yield mainly dioxane, whereas a similar treatment in the presence of an alkali hydroxide furnishes more highly polymerized materials of a waxy consistency. Other acid catalysts, such as aluminum hydrosilicate, may be employed for the same purpose in the presence of a solvent (dioxane or a hydrocarbon, ether or ester) at temperatures up to 150°C. in the liquid or vapor phase and at atmospheric or elevated pressure.[218] In like manner, propene oxide vapor is converted into a dimethyldioxane, b.p. 117°C., in the presence of a solid alkali bisulphate catalyst at about 120°C. More highly polymerized viscous liquid products are obtained under similar conditions in the presence of an alkali hydroxide.[219]

Dreyfus[220] discloses that *p*-dioxane, and its alkyl or other derivatives, may be prepared by the polymerization of the appropriate aldehydes under the influence of substances favoring etherification reactions. Examples of such materials are sulphuric acid, ferric chloride, zinc chloride, hydrogen chloride, benzenesulphonic acid, phosphoric acid, alkali bisulphates or acid phosphates. According to this method, *p*-dioxane is produced from formaldehyde while acetaldehyde furnishes dimethyl-*p*-dioxane.

Dreyfus also prepared cyclic ethers by condensation of polyhydric alcohols by means of hydrochloric acid.[221] The alcohol may be dissolved in an inert solvent to serve as a diluent capable of removing the ether in azeotropic mixture. In another process,[222] the glycol or other polyhydric alcohol is used in the form of its alkali or alkaline-earth salt, in which case heating at 160-200°C. in the presence of hydrogen chloride causes dehydration to the corresponding cyclic ether. Here, too, a diluent such as biphenyl is recommended as a means of distilling off the desired product, e.g., dioxane, from ethylene glycol or other di-alcoholate. Further, dioxane may be secured by heating β,β'-dichlorodiethyl ether with copper oxide and lead oxide.[222a]

A method for purifying commercial dioxane involves the removal of low-boiling aldehydes with a volatile inorganic acid.[223] The crude material is distilled with enough water and acid (hydrochloric, hydrobromic or sulphurous) to form a quaternary azeotrope. The undesired aldehyde and the acid pass over quantitatively in the first portions of the distillate. For example, from the following mixture:

96.25 vol. per cent	dioxane (containing 20% aldehyde
0.3 " " "	36% aqueous hydrochloric acid
3.45 " " "	water

all the aldehyde and hydrogen chloride came over at 86-89°C. in the first third of the distillate.

Dioxane has the constitution indicated by the formula

It is a neutral, inert, non-hydroxylic liquid of extensive solvent power. It has been recommended by Oxford[224] for use in the determination of molecular weights by the cryoscopic method. However, Roth and Meyer[225] consider the application of dioxane in this connection inadvisable, since its molar freezing point depression, approximately 4.71, was proven inconstant probably because of allotropy. These investigators found the heats of fusion and transition of pure dioxane to be —34.25 and —6.32 g.-cal. per gram, respectively. However, contrary to the general rule, the specific heat of the crystal was greater than that of the liquid.

The melting points, boiling points, refractive indices and densities of binary mixtures of water and dioxane have been determined by Gillis and Delaunois.[226] The melting point data showed a eutectic at —14.82°C., indicating formation of a definite hydrate. The dielectric constants of a series of dioxane-water mixtures between 0° and 80°C. for a wave length of 150 meters have been determined by Åkerlöf and Short.[227] A resonance method previously described by one of the workers was utilized.[227a]

In view of the increasing employment of dioxane as an industrial solvent, the pharmacological properties of the substance are of importance. von Oettingen and Jirouch[228] found that, in common with certain glycol derivatives, dioxane is toxic and possesses a haemolytic action on red blood corpuscles.

It has been shown by Fairley, Linton and Ford-Moore[229] that the *in vitro* final oxidation product of dioxane is oxalic acid with diglycolic acid as a by-product. Formation of these substances is held responsible for tissue injuries.

A detailed examination of the toxic properties of dioxane has been provided by Yant, Schrenk, Waite and Patty,[230] whose main findings may be summarized as follows. Dioxane is much more poisonous than ethylene glycol Exposure to its vapor produces severe irritation of the membranes of eyes and nose. After long exposure, the lungs are affected, narcosis being evident with high concentrations. It was concluded that the low toxicity of dioxane, as compared with carbon tetrachloride or tetrachloroethane, together with warning provided by its irritant nature, make health hazards from breathing its vapors very slight under ordinary conditions of usage and with reasonable exposure. The compound, however, must be deemed hazardous to life in air confined over the liquid in tanks, vats and wherever high concentrations may accumulate.

Dioxane is of interest chemically on account of the ease with which it yields addition compounds of the oxonium type. Thus, Doak[231] noted that with arsenic trichloride it forms a crystalline addition complex of the formula $(C_4H_8O_2)_3 \cdot 2AsCl_3$ (m.p. 62°C.). The latter compound is, however, largely dissociated into its components in benzene or acetone solutions

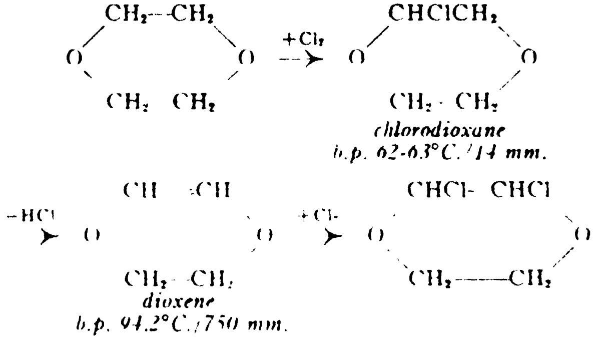
The products of chlorination of dioxane are the 2,3-dichloro- and a mixture of tetrachloro-derivatives. Kucera and Carpenter[232] found that chlorination in the presence of a little stannous chloride or iodine chloride at 90°C. yields 96.6 per cent of the 2,3-dichloro-compound. The latter could be further chlorinated (without a catalyst) at 145°C. to give an 83-85 per cent yield of a mixture of symmetrical and asymmetrical tetrachloro-compounds.

Summerbell and Bauer[233] consider the chlorination of dioxane to proceed via the monochloro-compound which then decomposes with the elimination of hydrogen chloride to yield dioxene, the complete scheme being:



In support of this mechanism it was observed that chlorodioxane prepared by the direct combination of dioxene with hydrogen chloride was unstable even at room temperature. These investigators have prepared various 2,3-diaryl-substituted dioxanes from the 2,3-dichloro-compound by the Grignard reaction. The 2,3-dihalide can be condensed with ethylene glycol to yield a mixture of two isomeric 2,3-ethylenedioxydioxanes.[234] A later report[235] by the same workers states that better yields of 2,3-dialkyldioxanes are secured if the magnesium alkyl bromide is first treated with an equimolar quantity of anhydrous zinc chloride or cadmium chloride.

Dioxane has been proposed[236] as an inert solvent in the etherification of alkali-cellulose by alkyl or aralkyl halides. Moncrieff and North[237] suggest the use of this liquid as a softening medium in the stretching of non-uniformly hydrolyzed cellulose ester yarns. The reagent is said to have a greater action on the less hydrolyzed portions. It is reported by Young and Perkins[238] that dioxane exerts a preferential solvent action on diolefin hydrocarbons and can thus be employed in the removal of butadiene from butenes and butanes. The separation can be effected by distillation of the hydrocarbon mixture countercurrent to a stream of solvent, the solution recovered being afterwards rectified. Dioxane has been suggested as a solvent for use in the preparation of a coffee extract.[239]

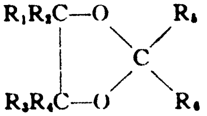
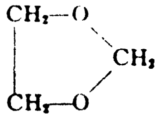
1,3-DIOXOLANES

The condensation of aldehydes or ketones with 1,2-glycols can be effected in the presence of esterification catalysts[240] to yield cyclic acetals or ketols (1,3-dioxolanes) of the general formula



where R_1, R_2, R_3, R_4, R_5 and R_6 may be alkyl groups or hydrogen atoms. The condensation is carried out by Dreyfus[241] in the presence of a limited amount of water, for example, 1 mole of water for each mole of aldehyde or ketone used. A continuous process for the manufacture of these cyclic products has also been described.[242] Acid sulphates, pyrosulphates or phosphates, especially of the alkali metals, are suggested as catalysts for the reaction. For example, interaction of ethylene glycol and paraformaldehyde may be effected continuously by sodium hydrogen sulphate at 140°C.[243] In this case, the product is 1,3-dioxolane,



This compound is said[244] to be applicable for dissolving cellulose acetates having an acetyl value higher than 56 per cent. The same solvent has been suggested as a medium for the incorporation of plasticizers or other materials into cellulose derivatives, such as the acetate having not less than 56 per cent acetyl value.[245]

In this connection it is interesting to note that the monoalkyl ethers of glycols may be condensed with formaldehyde by means of ferric chloride or mineral acids as catalysts. The products appear to be straight chain formals of the type

$$ROCH_2CH_2OCH_2OCH_2CH_2OR$$

For example, the addition of formaldehyde to ethylene glycol monomethyl ether gives bis-(β-methoxyethyl)methylene ether, b.p. 197-205°C. They are useful solvents, softeners and plasticizers for cellulose esters such as acetone-soluble cellulose acetate.[246]

MORPHOLINES

The morpholines are a series of cyclic ether amines somewhat closely allied, from the structural point of view, with the dioxanes. Morpholine itself has the constitution indicated by the following formula,

It was first prepared by Knorr[247] who dehydrated diethanolamine with 70 per cent sulphuric acid. In a somewhat analogous manner, Hampton and Pollard[247a] succeeded in securing morpholine in a reported yield of 48 per cent. In this case, diethanolamine was admixed with concentrated hydrochloric acid until the solution was acid to litmus. The mixture was heated to remove water, after which the temperature was raised to 200-210°C. for 15 hours. At the end of that time, the reaction mass was cooled and distilled with calcium oxide. The resulting liquid was dried over solid sodium hydroxide and refluxed with metallic sodium for 30 minutes. Fractionation of the liquid was effected and the portion boiling at 126-129°C. was collected. It may also be derived from β,β'-dihalogenodiethyl ethers by reaction with ammonia or amides.[248] The N-alkyl or aryl-substituted morpholines have been made from β,β'-dichlorodiethyl ether and primary aliphatic or aromatic amines. Thus, N-phenylmorpholine results from heating the halogenated ether with aniline,[249] a similar reaction also occurring in the case of β,β'-dibromodiethyl ether.[250] The condensation of β,β'-dichlorodiethyl ether with phenylhydrazine and other aromatic bases has been investigated by Axe and Freeman.[251]

Courtesy Industrial and Engineering Chemistry

FIG. 138.—Vapor Pressures of Various Amines. (A. L. Wilson)

Morpholine is a colorless liquid, b.p. 128.3°C., soluble in all proportions in water. It has a high and varied solvent power and has been suggested as a leveling agent in dye baths[252] and as a general textile assistant for scouring, stripping and boiling-off.[253] By virtue of its basic character, morpholine forms soaps with acids. The oleate and stearate are effective as stabilizers of oil-water emulsions.

According to Wilson,[254] morpholine was not commercially available as a solvent until 1935. It has a penetrating but not unpleasant odor suggestive of ammonia. It absorbs both moisture and carbon dioxide from the air, forming a carbamate which can be sublimed almost unchanged on heating at 95-100°C. It is water-soluble, cannot be "salted out" though it becomes immiscible with strong solutions of sodium hydroxide. A 95 per cent aqueous morpholine is in equilibrium with a 50 per cent solution of caustic soda.

Combinations of morpholine with many acidic bodies seem to be loosely held, since the amine may be recovered by distillation from its addition products with oleic acid or phenol. Water solutions of its salts with weak gaseous acids give up morpholine on boiling.

The soaps serve especially well in the production of coating emulsions, certain types of films exhibiting water-resistance.

TABLE 122.—*Some Physical Constants of Morpholines.*

Compound and Formula	Specific Gravity 20°/20°C.	Boiling Point (760 mm.) °C.	Vapor Pressure 20°C. mm.
Morpholine, $NH(C_2H_4)_2O$	1.0016	128.3	13.2
Methylmorpholine, $CH_3N(C_2H_4)_2O$	0.9051	115.4	16.0
Phenylmorpholine, $C_6H_5N(C_2H_4)_2O$	——	260.0	..
Morpholine ethanol, $HOC_2H_4N(C_2H_4)_2O$	1.0724	225.7	0.11

Morpholine vinyl ether, $C_2H_3OC_2H_4N(C_2H_4)_2O$	1.0023	210.1	0.3

SOLVENT PROPERTIES OF MORPHOLINES

Morpholine is miscible in all proportions with water, alcohol, glycols, glycol ethers, acetone, methyl butyl ketone, ethyl ether, butyl ether, benzene, turpentine, pine oil, castor oil, linseed oil, paraffin wax (hot) and saturated brine. It dissolves over 5 per cent of naphtha, shellac, rosin, ester gum, copal gum, a number of vinyl resins, cellulose acetate or nitrate, benzyl cellulose, alcohol-soluble and oil-soluble dyes. It will dissolve from 1 to 5 per cent of sulphur but less than 1 per cent of paraffin oil, beeswax, or water-soluble dye.

Morpholine ethanol has the same solvent properties as morpholine with the following exceptions: it dissolves less than 1 per cent of naphtha, from 1 to 5 per cent of rosin, over 5 per cent of linseed oil and forms gels with several vinyl resins.

Morpholine ethyl ether is an even more general solvent than morpholine as it adds naphtha and paraffin oil to the "miscible in all proportions" list, given for the latter. It dissolves from 1 to 5 per cent of paraffin wax, beeswax and Vinylite A. Over 5 per cent of gum dammar may be dissolved, whereas the gum is only soluble in part in the other morpholines. Two other differences from the morpholine characteristics are to be noted, viz., less than 1 per cent of water-soluble dye or cellulose acetate are dissolved in this ether. It may serve as a corrosion inhibitor in water solutions, as a light stabilizer for trichloroethylene, as an antiknock agent for gasoline, as a carbon remover for use on aluminum pistons, and possibly as an assisting agent in permanent waving.

[253] H. Ulrich and J. Nuesslein, U. S. P. 1,923,179, Aug. 22, 1933; *Chem. Abs.*, 1933, 27, 5207.

[254] A. L. Wilson, *Ind. Eng. Chem.*, 1935, 27, 867; *Brit. Chem. Abs.* B, 1935, 893; *Chem. Abs.*, 1935, 29, 6571.

Of the morpholine derivatives the ethyl and vinyl ethers are the only compounds known to surpass morpholine in solvent power. Both ethers yield constant-boiling mixtures with water, a somewhat rare phenomenon considering their high boiling points. These solutions boil at about 99°C. and contain approximately 12 per cent amine. The vinyl ether is hydrolyzed completely in acid solution to morpholine ethanol and acetaldehyde.

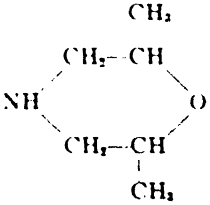
The ethyl ether is a mobile, colorless liquid and very stable. It has been suggested as a high-boiling reaction solvent in metatheses that set free acids and in the Grignard synthesis.

Phenylmorpholine, a white crystalline solid when pure, offers promise as a dye intermediate. It may serve as a coupling agent for diazotized compounds, especially in cases where the alkyl anilines are unstable due to migration of alkyl groups. Methyl morpholine, a non-reactive tertiary amine, has advantages as a solvent on account of its relatively low boiling point and density. It is less reactive than morpholine and more easily recovered. It may supply a substitute for ethyl ether or pyridine as a reaction solvent or as a catalyst.

A comparison of the vapor pressures for some morpholines with those of some aliphatic amines is given in Fig. 138.

DIMETHYLMORPHOLINE SYNTHESIS

Krasuskii[255] treated propene oxide with aqueous ammonia at 0-20°C. to obtain di-β-hydroxypropylamine, $(CH_3CHOHCH_2)_2NH$. This compound was then heated in a closed tube with 70 per cent sulphuric acid for 8 hours at 160-170°C. Steam distillation of the resultant reaction mixture, followed by caustic soda neutralization of the residue and steam distillation of the neutral liquor, yielded dimethylmorpholine.



The boiling point of the above compound (d_4^0 0.935), after purification by means of the hydrochloride salt and two distillations over metallic sodium, was 144°C. A yield of 4 g. of the morpholine was obtained by the above method from 16 g. of the dihydroxypropylamine.

Mono- and trihydroxypropylamines were prepared by Krasuskii in the course of the synthesis. The purified mono-amine (d_0^0 0.9769) boiled at 159.2-159.5°C. at 748 mm. The di-amine boiled at 249-250°C. (745 mm.) and had a melting point of 44.5-45.5°C. and d_{25}^{25} (liquid) 1.0038. The tri-amine (b.p. 190°C. at 23 mm.) melted at 48-50°C. and was soluble in water, ethyl alcohol and ether. Its hydrochloride melted at 186-188°C.

Attempts to prepare tetramethylmorpholine from isobutene oxide and hexamethylmorpholine from trimethylene oxide were unsuccessful.

[255] K. Krasuskii, *J. Gen. Chem. (U.S.S.R.)*, 1936, **6**, 460; *Brit. Chem. Abs.* **B**, 1936, 972; *Chem. Abs.*, 1936, **30**, 6377.

Propene Oxide and Derivatives

Propene oxide may be produced[256] by the direct oxidation of propene with oxygen in the presence of inert gases, e.g., nitrogen or carbon dioxide, at 300-375°C. under the catalytic influence of metals such as silver, silver and gold, or silver, gold and copper. Air may be used in the place of oxygen and a large proportion of carbon dioxide is recommended. The latter not only acts as a diluent but inhibits further reaction. The pressure used is above normal, in some cases as high as 50 atmospheres. The catalyst may be applied in the colloidal state in water. A typical reaction mixture was composed of 66 per cent oxygen and 24 per cent nitrogen. In one instance, colloidal silver (with small proportions of gold or copper or both) was placed in a high-pressure tube filled with water. After forcing propene gas into the water to form a solution, the tube was heated to 300-375°C., while air was pumped into the reaction vessel.

When propene oxide, and higher alkene oxides, are passed in vapor form over certain catalysts at elevated temperatures, isomerization to aldehydes takes place. Substances of large surface area, such as wood charcoal, active charcoal, alumina gel, silica gel and permutites, are suggested[257] for effecting this isomerization. Bauer[258] describes the conversion of propene oxide into propionaldehyde and other substances by passage in vapor form at 150-450°C. over catalysts. For this purpose he uses non-volatile, stable metallic compounds of oxygen-containing acids derived from elements of Groups 5 and 6, such as magnesium pyrophosphate associated with kieselguhr. According to Hoffmann,[259] propene oxide undergoes conversion into propionaldehyde to the extent of 70 per cent when passed in vapor form at 300°C. over silica gel or a silicate of large surface.

Alkene oxides of 3 to 4 carbon atoms, such as propene oxide and isobutene oxide, have been proposed as ingredients of an adhesive and softening composition for shoes.[260] Instead of isomerizing to propionaldehyde, propene oxide may be converted into allyl alcohol. It is reported by Young and Law[261] that passage of the diluted propene oxide vapor over a catalyst at 200-400°C. results in the production of this alcohol and propionaldehyde in approximately equal proportions. Nitrogen or steam may serve as the diluent and alumina, thoria or titania as the catalyst. Norton and Hass[261a] point out that propene oxide reacts with diethyl magnesium to furnish 2-pentanol, and with ethyl magnesium bromide to form a mixture of 2- and 3-pentanol.

n-Propyl Alcohol. On catalytic hydrogenation, propene oxide is converted exclusively into *n*-propyl alcohol. This somewhat unexpected reaction provides an excellent method for the synthesis of what is, from a practical viewpoint, a rather inaccessible alcohol. In the process of Young and Law,[262] the oxide diluted with steam is conducted over alumina at about 275°C. with a space velocity of 48-120 reciprocal hours. Subsequently, the gaseous mixture plus 4 volumes of hydrogen (calculated on the oxide fed) is led over a reduced-nickel catalyst at about 150°C.

Propene Dinitrate. By adding propene oxide very slowly to cooled fuming nitric acid and then pouring the mixture into hot water, Henry[263] obtained an oily, colorless liquid he termed propene dinitrin and gave $C_3H_6(NO_3)_2$ as its formula. A dinitrate was produced from amylene oxide by a similar procedure.

Amines. Combination of propene oxide with aqueous ammonia produces mono-, di- and triisopropanolamines as well as more complex substances formed by reaction of the hydroxyl groups of these bases. Wickert[264] explains that the production of the latter compounds may be minimized by maintaining the temperature at or below 55°C. It is also desirable to avoid an excess of unchanged oxide in the mixture. Another process for the manufacture of isopropanolamines has been disclosed by Wickert[265] in which propene oxide is bubbled through porous porcelain into 28 per cent aqueous ammonia kept below 55°C. (45-55°C.). Use of an excess of oxide leads to violent exothermic reaction and further condensation of the products. When the proportion of propene oxide is about 80 per cent of that required to form the tri-compound, the resulting mixture of bases is stated to contain more than 90 per cent of triisopropanolamine as well as mono- and di-derivatives which can be recovered by vacuum distillation.

The use of anhydrous mono- or dipropanolamine for the removal of carbon dioxide from industrial gases has been described by Smola.[266] Like triethanolamine, tripropanolamine forms addition products and alcoholates by reaction with metallic salts such as cobalt chloride. A number of such metallic compounds have been prepared by Tettamanzi.[267] Complex derivatives made by condensation of propene and butene oxides with β,γ-dihydroxypropyl-*m*-toluidine and similar bases have been reported by Lange.[268] For example, (γ-methoxy-β-hydroxypropyl)-aminobenzene treated with butene oxide at 170-180°C. produces the hydroxybutyl derivative which boils at 205-208°C. (10 mm.).

Reaction products of propene oxide with ammonia or with organic hydroxy-, carboxy-, amino- or hydroxyalkylamino-compounds may be condensed at 100 to 150°C. with urea, thiourea, guanidine or their derivatives.[269] A derivative of guanidine-propene oxide may be used in printing vat dyes. Dihydroxypropylglycolic ether plus methyl guanidine furnishes a sizing agent for viscose rayon. Isopropyl urea combined with trihydroxyethyl sorbite produces a cleaning and emulsifying agent.

Numerous water-soluble condensation products applicable as assistants in the textile and related industries may be prepared by use of alkene oxides in single or successive combinations with aliphatic organic hydroxylated substances.[270] The latter should have at least 5 carbon atoms or should be amines having one reactive —NH group. The products may be rendered more soluble in water by sulphonation. As instances of the above condensations, cetyl alcohol, *n*-$C_{16}H_{33}OH$, may be combined with propene oxide in the proportion of 1:6 moles. After an addition of

2 moles of ethylene oxide, the product may be treated with chlorosulphonic acid in carbon tetrachloride at below 10°C. Similarly, stearic acid, treated in turn with 3 molar proportions each of ethylene, propene and then ethylene oxides, supplies a material for softening and finishing viscose rayon. If 1 part of cetylamine is reacted with 4 of ethylene oxide and again with 12 to 16 parts of propene oxide, the condensate may be utilized in dyeing wool.

The reactivity of such diverse materials as silk, wool, furs, feathers, fibroin silk, casein and gelatine toward acid-treating agents is said to be increased by the action of alkene oxides or their derivatives on them.[271]

Cellulose hydroxypropyl phthalate and similar hydroxy aliphatic esters of various dicarboxylic acid esters of cellulose have been produced by Malm and Fordyce.[272] Cellulose phthalate is allowed to react with propene oxide for 24 hours at 100°C. to secure the above mentioned ester. Hydroxyalkyl derivatives of cellulosic materials such as cotton or a bisulphite pulp in sheets may be obtained by interaction with an alkene oxide in the absence of bases, provided a catalytic salt is present.[273] Contact media suggested for the purpose are as follows: an alkali metal, zinc acetate or chloride, magnesium chlorate, calcium or barium sulphocyanide, or a halide of a heterocyclic tertiary amine, such as benzylpyridinium chloride. The cellulose derivatives may be formed into sheets or used for esterification.

THE HIGHER OLEFIN OXIDES

Few of the higher aliphatic olefin oxides have received close study, probably on account of the difficulty of their preparation. In this connection it is interesting to note that small amounts of olefin oxides (probably butene-2 oxide) have been found in the products of oxidation of butene-2 with oxygen in Pyrex tubes at 375-490°C.[274]

Batalin and Ugryumov[275] secured a 76-81 per cent yield of butene-2 oxide by interaction of the corresponding halohydrin with 40-50 per cent aqueous sodium hydroxide at 75-90°C. The product boiled at 55-58°C. and had d_0^0 0.8306. Brockway and Cross[275a] report that *cis*-butene-2 oxide boils at 54°C. at 747 mm. while *trans*-butene-2 oxide boils at 60°C. under the same pressure. Isomerization of the oxide in aqueous solution at 150°C. furnished methylethyl ketone. Treatment with 5 moles of ammonia (as a 25 per cent aqueous solution) gave, after 100 hours at 38°C., 41.5 per cent mono- and 40 per cent dibutanolamine. The proportion of the mono derivative could be increased to 66 per cent when 3 moles of the oxide and 1 mole of (aqueous) ammonia were interacted for 6 hours at 100°C. Both amines were soluble in water, ether and alcohol. Tributanolamine, a viscous colorless mass, was only slightly soluble in water, and its solubility decreased with increase in temperature. The boiling points and densities of the three butanolamines are given in Table 123.

On reacting with diethylmagnesium, butene-2 oxide was said to form 3-methyl-2-pentanol.[275b]

Dibutanolamine	240-250°C. (at 753 mm.) 150-152°C. (at 20 mm.)	0.9809
Tributanolamine	200-201°C. (at 20 mm.)	0.9975

Walti[276] obtained the oxides of butene-1 and pentene-1 by the action of hot aqueous alkali on 1-chlorobutanol-2 and 1-chloropentanol-2, respectively. Hexene-1,2-oxide was prepared by refluxing the corresponding chlorohydrin in anhydrous ether solution with powdered potassium hydroxide. Walti found that pentene-1,2-oxide reacts readily with a 30 per cent aqueous solution of dimethylamine to yield 1-dimethylaminopentanol-2. Hexene-1,2-oxide combines rapidly with 48 per cent hydrobromic acid in the cold and is thus converted into 1-bromohexanol-2. The combination of isobutene oxide with dibenzylamine has been shown to furnish 1-dibenzylamino-2-methyl-2-propanol.[277]

Like the lower olefin oxides, some of the higher members undergo isomerization to the corresponding aldehydes or ketones. When heated with zinc chloride at 315°C., pentene-2,3-oxide and heptene-3,4-oxide are isomerized to methyl-*n*-propyl ketone and ethyl-*n*-butyl ketone, respectively.[278]

The products of the reaction between magnesium dimethyl or diethyl with cyclohexene oxide at 100°C. in ethereal solution consist, after hydrolysis, of *trans*-2-methylcyclohexanol or *trans*-2-ethylcyclohexanol, respectively.[279]

Cyclohexene oxide has been produced by Bartlett[280] on treatment of the *trans*-chlorohydrin of cyclohexene with cold methyl alcohol. When the oxide was treated with hydrogen chloride or cyclohexene with hypochlorous acid, the *trans* form of the cyclic chlorohydrin was obtained.

The oxide of $\Delta^{1,3}$-cyclohexadiene has been prepared from the dibromide of the cyclic compound by Bedos and Ruyer.[281] The dihalogen derivative was submitted to successive treatments with silver acetate and dry powdered potassium hydroxide in diethyl ether. The oxide was found to react slowly with perbenzoic acid to form the dioxide. It was not possible to decolorize bromine in carbon tetrachloride immediately with the oxide except in the presence of a little water. By treatment of the oxide with phosphorus pentabromide in ether, the original dibromide (m.p. 108°C.) could be regained as well as a liquid isomer.

The higher olefin oxides have, so far, attracted little attention either from scientific or industrial investigators. However, a few derivatives of these substances have been suggested for use in special applications.

The condensation of isobutene oxide with anhydrous alcohols, e.g., methyl or ethyl, can be effected by heating in the presence of a catalyst such as sulphuric, nitric or phosphoric acids. The products are the corresponding monoalkyl ethers of isobutene glycol, which boil above 140°C. and are said to be applicable as solvents for gums, resins, lacquers and cellulose esters.[282]

Dreyfus[283] proposes to make a material which can be used in the manufacture of rayon films and lacquers by reacting an alkene oxide, for instance, butene oxide, with a mixed aliphatic ester of cellulose.

Chapter 24

Miscellaneous Reactions of Olefins (I)

A number of addition reactions of the simple olefins with sulphuric acid, halogens and halogen acids have already been discussed.[1] In the following account some further reactions of these olefins, mostly of an additive character also, will be described. Among the compounds with which olefins condense are included aromatic hydrocarbons, paraffins, naphthenes, phenols, acids, acid halides, ammonia, and amines.

CONDENSATION OF ALKENES WITH AROMATIC HYDROCARBONS

Many investigations have shown that the Friedel-Crafts reaction for the alkylation of aromatic hydrocarbons may take place with the intermediate formation of an addition complex.[2] The direct alkylation of aromatics by alkenes in the presence of acid catalysts is a particular reaction of these hydrocarbons which has received considerable attention. A discussion of such perhaps is best systematized on the basis of the catalysts employed. The more important of these are sulphuric acid, phosphoric acid, phosphorus pentoxide, aluminum chloride and boron fluoride.[3]

Use of Sulphuric Acid. Alkylation in the presence of this acid was first investigated by Kraemer and Spilker[4] and Brochet,[5] who showed that the acid provided a convenient procedure for the preparation of some alkyl benzenes. Brochet believed that the method was general, although his results were obtained with hexene and benzene. Ipatieff, Corson and Pines,[6] however, have observed that this reaction is not applicable for the ethylation of benzene even under pressure. They investigated the effect of using sulphuric acid of both 96 and 80 per cent concentration as catalysts for propylation of benzene, and found that with the more concentrated acid interaction was largely alkylation, with only slight ester formation. On the other hand, when 80 per cent acid was employed, alkylation and formation of the alkyl sulphate occurred to about the same degree. With isobutene and benzene and acid of 96, 80 and 70 per cent concentration, the predominant reactions were alkylation, polymerization of the olefin to triisobutylene and formation of alkyl sulphate, respectively. The extent of alkylation was shown to depend more or less on the concentration of the olefin in the reacting liquid. The results obtained when 96 per cent sulphuric acid was used as a catalyst for the propylation of benzene are given in Table 124.

Some of the higher alkenes, namely, butene-1, pentene, octene, nonene and dodecene, were substituted for propene. The structures of the products were not

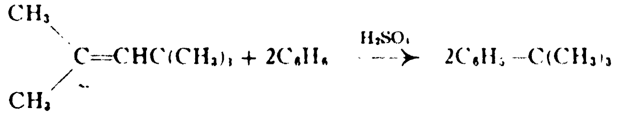
TABLE 124.—*Propylation of Benzene.*

Run	Vol. of 96% H_2SO_4	Vol. of Benzene	Grams of Propene	Ratio of Mono- to Di-isopropylbenzene
1	100 cc.	200 cc.	110 g.	1.4
2	100 cc.	400 cc.	110 g.	3.9
3	250 cc.	1000 cc.	300 g.	6.3

determined in all cases. Diisopropyl-, di-*ter*-butyl- and di-*sec*-butyl-benzene, and isopropyltoluene, however, were all shown to have the substituents in the 1 and 4 positions by oxidation to either terephthalic or *p*-toluic acids or by nitration. Tetraisopropyl benzene (obtained in this investigation) was believed to be identical with the 1,2,4,5-derivative previously described by Berry and Reid.[7] The temperature at which alkylation was effected varied between 0 and about 20°C. in most cases. However, in the attempted propylation of benzene, using 80 per cent sulphuric acid as a catalyst, the reaction was allowed to proceed at 60°C. Furthermore, in preparing higher homologues from diisopropylbenzene, using 96 per cent acid, the temperature also was permitted to rise to 60°C. In treating naphtha fractions (boiling 90° to 95°C. and 125° to 130°C.) from brown coal with sulphuric acid of different concentrations, Geissler[8] employed a temperature of 10° to 15°C. The high boiling oils which were obtained when 90 per cent acid was used as a treating agent were found to be the condensation products of toluene with heptene and octene.

When alkylation of benzene was attempted using di- or tri-isobutylene with 96 per cent sulphuric acid as a catalyst, mono-, *p*-di- and higher *ter*-butyl-benzenes were obtained. Ipatieff and Pines referred to this type of reaction as a "depolyalkylation."



$$(CH_3)_2C{=}CHC(CH_3)_3 + 2C_6H_6 \xrightarrow{H_2SO_4} 2C_6H_5{-}C(CH_3)_3$$

As an example, 140 g. of diisobutylene and 97 g. of benzene were added during about 1½ hours to 100 cc. of 96 per cent sulphuric acid in a flask cooled by an ice bath. The reaction mixture separated into two layers. The hydrocarbon layer weighed 214 g. after washing and drying. Fractions corresponding to mono-, di- and tri-*ter*-butyl benzene were obtained by distillation. Similar results were also secured using aluminum chloride as the catalyst.[9]

Truffault[10] has reported the alkylation of benzene by cyclohexene in the presence of concentrated sulphuric acid. The reaction proceeds according to the following equation:

$$C_6H_6 + C_6H_{10} \xrightarrow{H_2SO_4} \underset{(b.p.,\ 104\text{-}106°C.)}{C_6H_5{-}C_6H_{11}} + \xrightarrow{C_6H_{10}} \underset{\substack{p\text{-dicyclohexylbenzene} \\ (m.p.,\ 102\text{-}103°C.)}}{C_6H_{11}{-}C_6H_4{-}C_6H_{11}}$$

He also found that it was possible to cause a condensation of halogenated ethylene derivatives with benzene to form ω-haloalkylbenzenes of interest in synthetic work, particularly in the preparation of amides and carboxylic acids.

Naphthalene is said to be propylated by reaction with propene in the presence of naphthalene sulphonic acid[11] or of sulphuric acid. Naphthalene sulphonic acid itself may also be propylated in this way.[12] The products obtained by the condensation of cycloolefins (b.p. from 85° to 120°C.) and naphthalene are said to be useful for breaking petroleum emulsions.[13] On the other hand, Schildwächter[14] has stated that a good lubricating oil may be prepared by the condensation of ethylene with a coal-tar fraction boiling between 200° and 300°C. The viscosity was still further increased by treatment with the silent electric discharge. Oil made by this method was reported to show stability against oxidation and high temperatures.

Ipatieff[15] has described several procedures for increasing antiknock properties of gasoline by treating straight-run or cracked distillates with the gases from cracking operations and catalysts of either sulphuric acid or acid sludges. Some alkylated compounds are said to be formed. He has also suggested[16] that the reaction of aromatic hydrocarbons with olefins in the presence of sulphuric acid may be used to remove gum-forming olefins from fuel gases. After the treatment both the purified gas and the aromatic derivatives are utilized. Ipatieff[17] has recommended a mixture of sulphuric and phosphoric acids to catalyze the alkylation of a cyclic hydrocarbon (such as benzene) by olefinic substances, e.g., propene or cracking gas. The products could be employed in motor fuels. He has also used phosphoric acid to remove sulphuric acid esters dissolved in the hydrocarbon liquid after alkylation of an aryl hydrocarbon with a sulphuric acid catalyst.[18]

Use of Phosphoric Acid. Alkylated aromatics which had good antiknock properties were obtained by treating benzene with the gases from oil-cracking, using phosphoric acid as the contact agent.[19] The influence of the latter compound on condensations involving low-molecular weight olefins has been studied by Ipatieff, Pines and Komarewsky.[20] They reported that ethylation could be effected using this catalyst at 300°C. For example, a reaction was carried out in a glass-lined, electrically-heated, rotating autoclave. For a run employing 314 g. of benzene in a container of 3 liters capacity, ethylene was added until the total pressure was 60 atmospheres at 21°C. The catalyst was 103 g. of 85 per cent phosphoric acid. Reaction continued for 12 hours, and 569 g. of liquid product were obtained. This was fractionated and gave mono-, di-, tri- and tetra-ethyl benzenes. The structures of the di- and tri-derivatives were shown to correspond to the 1,3- and 1,3,5-compounds, respectively.

For the treatment of gasolines (having a high content of aromatics) with olefin-containing gases in the presence of pyrophosphoric acid, see V. Ipatieff, U. S. P. 2,067,764, Jan. 12, 1937, to Universal Oil Products Co.; *Chem. Abs.*, 1937, **31**, 1603.

The alkylation of higher homologues was also carried out successfully. Ethylation of naphthalene and tetrahydronaphthalene was accomplished under pressure at 300°C. using 85 per cent phosphoric acid. Propylation was effected with 89 per cent acid and a temperature of 200°C. Almost 90 per cent of the propene was taken up by naphthalene, although 27 g. of fluorene gave only 9 g. of propyl fluorene when treated with 40 g. of propene and 25 g. of acid.

Phosphorus Pentoxide as Catalyst. Previous to the work of Ipatieff, Pines and Komarewsky on phosphoric acid, Malishev[21] had observed the catalytic effect of phosphorus pentoxide on the alkylation of benzene. For example, 708 g. benzene, 50 g. phosphorus pentoxide, 24 g. lampblack (to maintain the catalyst in colloidal suspension) and 10 g. cresol (to peptize the lampblack) were heated for 100 minutes at 250°C. with agitation, and ethylene added in sufficient quantity to maintain a pressure of 27 atmospheres. The product, 527.7 g. of liquid, was fractionally distilled. The volume per cent composition of the distillate was: 1.6 per cent benzene, 18.2 per cent ethyl benzene, 42.3 per cent diethyl benzene, 24.4 per cent triethyl benzene and 8.5 per cent of higher isomers. From the last fraction, 34 g. of hexaethyl benzene was isolated. Experiments were also conducted employing benzene and isobutene, toluene and propene, and naphthalene and ethylene. Reaction in each instance was carried out in essentially the manner just described. The temperature was kept between 200 and 250°C., except in the propylation of toluene which was carried out at 150°C. to give *p*-cymene. The only product from these experiments which was identified was 1,4-*di-ter*-butyl benzene (m.p. 76°C.).

Treatment of cracked gasoline with phosphorus pentoxide (and carbon black) may be employed as a method of refining.[22] This procedure appears to comprise alkylation of the aromatic and naphthenic constituents as well as polymerization of the olefins. There is an increase in octane rating and decrease in bromine number of a distillate refined in this manner, as is shown in Table 125.

That there is a difference between the effects of phosphorus pentoxide and metaphosphoric acid is shown by the polymerization of ethylene by the former under 50 atmospheres pressure and at 250°C. to a gasoline-like liquid containing many types of hydrocarbons. This polymerization, however, apparently is hindered when aromatic hydrocarbons are present and may even be reversed, since under these conditions diisobutylene gives rise to, for example, isobutyl benzene. Refining may be carried out by distilling the gasoline through a stirred suspension of 1 to 2 per cent phosphorus pentoxide in a heavy unrefined mineral oil.

The effect of phosphoric anhydride on unsaturated compounds has also been observed by Truffault.[23] He found that extraction of the oxide with cyclohexene (in a Soxhlet apparatus) gave 80 to 90 per cent of cyclohexylcyclohexene [b.p. (760 mm.) 238-239°C., n_D^{20} 1.493, d^{20} 0.904]. With ethylene or propene and benzene it was possible to obtain the corresponding alkylated benzenes, but substitution of these olefins by pentene or cyclohexene gave mostly dimers of the latter.[24]

Application of Aluminum Chloride. In addition to its well-known use as a catalyst in the Friedel-Crafts reaction, aluminum chloride may be employed in the alkylation of aromatics by olefins, particularly for the preparation of monoalkyl[25] and monocyclohexyl benzenes.[26] Deposited on a siliceous carrier, the metallic chloride has served as a contact agent for the formation of alkyl benzenes in gasolines to improve the antiknock qualities of the latter.[27] When mixed olefins are the alkylating agents it is suggested that interaction between aromatics and the higher unsaturated hydrocarbons be carried out in the presence of sulphuric acid, after which any residual ethylene can then be combined with the cyclic compounds by the aid of aluminum chloride.[28]

Another method which has been proposed comprises partially chlorinating a paraffin, eliminating hydrogen chloride from the chloro compound by heating with ferric chloride and condensing the resulting olefin with an aromatic compound.[29] Nitrogen-containing cyclic substances, e.g., carbazole, are said to be alkylated at 50° to 200°C .in the presence of aluminum or ferric chloride to mono- or polyalkyl derivatives of an oily or resinous character.[30]

Materials for addition to lubricating oils have been prepared by treating polynuclear aromatics with olefins (using 20 per cent or more of aluminum chloride) at 50° to 250°C. The product is then hydrogenated to give a mixture of compounds which is reported to induce fluorescence when dissolved in hydrocarbon oils.[31] According to Shaffer and Fasce,[32] anthracene is added to the extract from the treatment of petroleum distillates with liquid sulphur dioxide and the mixture heated with aluminum chloride at 100° to 200°F. for several hours. Hydrolysis is then effected at 180°F. by agitation with aqueous hydrochloric acid. The slurry is filtered and the filtrate washed with water. The product is then dried and distilled to yield a material which is said to give a green fluorescence to lubricating oils and to improve the cast and pour point as well.

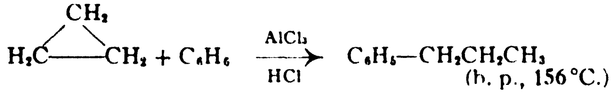
Cyclopropane is very similar in its reactions to an unsaturated hydrocarbon, and Grosse and Ipatieff[33] have found that it undergoes the same type of reaction with aromatics as do olefins, namely, the formation of an alkylated derivative. The product, however, instead of being a branched-chain substance is the *n*-alkyl derivative formed in the following manner:



Interaction may proceed to complete alkylation, and the hexapropylbenzene (m.p., 103°C.; b.p., 325°C.) has actually been isolated.

Although aluminum chloride is probably the most generally used metallic chloride, nevertheless Grosse and Ipatieff[33a] call attention to the application of other catalysts of this type. These include beryllium chloride, the tetrachlorides of titanium, zirconium and hafnium, and the pentachlorides of columbium and tantalum. Of these the titanium salt was the least effective.

Boron Trifluoride as Catalyst. This compound has been used as a catalyst for polymerization and other reactions of olefins[34] and in general is similar to aluminum chloride in its effect. For example, it is said to be possible to obtain intermediates for dyes or for the manufacture of wetting agents by treating an olefin and an aromatic hydrocarbon with the substances obtained by interaction of boron trifluoride with water, an alcohol or an acid.[35] Slanina, Sowa and Nieuwland[36] have reported that boron trifluoride accelerated the alkylation of benzene by propene. The greatest extent of reaction was obtained using either phenol or sulphuric acid with the halide. Other secondary catalysts (or promoters) were not so effective, but became increasingly so as their acidity increased. Thus, trichloroacetic acid was somewhat more active when used with boron trifluoride than was acetic acid. The important difference which was observed between the boron and aluminum halides was, whereas the latter gives a *m*-dialkyl compound, the former gives a *p*-dialkyl derivative.

Using sulphuric acid and boron trifluoride, Nieuwland and his co-workers succeeded in preparing isopropyl- and isobutylbenzenes, *p*-cymene (from toluene), and an isopropylnaphthalene of undetermined structure (b.p., 260-270°C.). It was found that ethylene did not work very well in these reactions. Ipatieff, Corson and Pines[37] found that sulphuric acid catalyzes the alkylation in the same manner as it does when admixed with boron trifluoride. However, Ipatieff and Grosse[38] reported later that boron trifluoride alone was also efficacious. For example, 250 cc. of benzene, 18.5 g. of the trifluoride and 2 g. of water were treated with ethylene at 20 atmospheres pressure for 8 hours at 20° to 25C°. More than 25 per cent of the aromatic was converted into monoethylbenzene (mainly), diethylbenzene and higher alkylated bodies. The effect of the acid-halide catalyst was studied further by Wunderly, Sowa and Nieuwland.[39] Experiments were conducted in the apparatus shown in Fig. 139, using 2 moles of benzene and adding propene at a carefully controlled rate. The temperature was 4°C.(±1°) and the time of contact 2 or 4 hours. In all instances, 80 g. of sulphuric acid were used (as catalyst) and in some cases 10 g. of boron trifluoride were added. The results are given in Table 126.

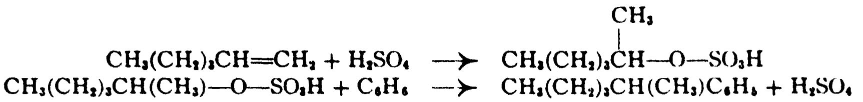
TABLE 126.—*Effect of Boron Trifluoride on Olefin-Benzene Reaction.*

Grams of H_2SO_4	Grams of BF_3	Time in Hours	Isopropylbenzene Obtained in Grams Mono-	Di-	Tri-
80.0	0.0	2	62.9	22.8	7.7
80.0	10.0	2	91.1	32.7	5.2
80.0	0.0	4	97.1	56.2	20.3
80.0	10.0	4	97.1	82.4	22.9

To determine the course of the reaction, benzene was refluxed with purified diisopropyl sulphate. At the end of an hour no layer had separated, and this was considered evidence that no interaction had occurred. Addition of a small proportion of sulphuric acid, however, caused violent combination to take place and the separation of a large layer. Brochet[40] suggested the mechanism (using α-hexene) to be represented by:

---

[39] H. L. Wunderly, F. J. Sowa and J. A. Nieuwland, *J.A.C.S.*, 1936, **58**, 1007; *J. Inst. Pet. Tech.*, 1936, **22**, 394A; *Brit. Chem. Abs.* **A**, 1936, 975; *Chem. Abs.*, 1936, **30**, 5191.



$$CH_3(CH_2)_3CH{=}CH_2 + H_2SO_4 \longrightarrow CH_3(CH_2)_3\overset{\overset{CH_3}{|}}{C}H{-}O{-}SO_3H$$
$$CH_3(CH_2)_3CH(CH_3){-}O{-}SO_3H + C_6H_6 \longrightarrow CH_3(CH_2)_3CH(CH_3)C_6H_5 + H_2SO_4$$

Wunderly, Sowa and Nieuwland disagreed with the last step. They believed that if this were the case, it should be possible to prepare *n*-propyl benzene if benzene were treated with *n*-propyl acid sulphate and di-*n*-propyl sulphate, using boron trifluoride as a catalyst. The products obtained in this way were not, however, *n*-propyl, but isopropyl benzenes and the proposed mechanism was therefore given as:

$$CH_3CH_2CH_2O{-}SO_3H \longrightarrow (C_3H_6) + H_2SO_4$$
$$(C_3H_6) + C_6H_6 \xrightarrow{(H_2SO_4)} (CH_3)_2CH{-}C_6H_5$$

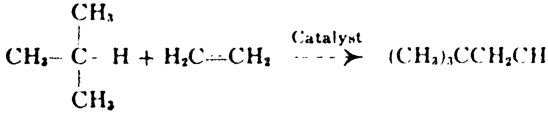
where (C_3H_6) represents an intermediate activated olefin stage which reacts readily with benzene.

CONDENSATION OF OLEFINS WITH PARAFFINS

Thermal decomposition of paraffins in the presence of catalysts to give a lower paraffin and an olefin has received considerable attention (see Chapters 2, 3, 4), but it has generally been considered that the reverse reaction would not occur very readily. Ipatieff and Grosse[41] have reported that paraffins, naphthenes, aromatics and olefins interact with surprising ease amongst themselves in the presence of halides of aluminum, boron, beryllium, titanium, zirconium, hafnium, thorium, columbium and tantalum. That change between paraffins and olefins takes place according to the general equation:

$$C_mH_{2m+2} + C_nH_{2n} \xrightarrow{\text{Catalyst}} C_{m+n}H_{2(m+n)+2}$$

or, as a specific example:



$$CH_3{-}\underset{\underset{CH_3}{|}}{\overset{\overset{CH_3}{|}}{C}}{-}H + H_2C{=}CH_2 \xrightarrow{\text{Catalyst}} (CH_3)_3CCH_2CH_3$$

However, combination proceeds as readily and smoothly as these equations suggest in only very few cases under very carefully controlled conditions. In most instances, complicating side-reactions occur. For example, the paraffin (C_nH_{2n+2}) formed initially may react with another molecule of ethylene to give a paraffin $(C_{n+2}H_{2n+6})$ which may continue to give higher homologues. In certain cases the paraffin may be split by the action of the catalyst to yield an olefin and another paraffin molecule. The former could then unite with a paraffin molecule to furnish a new aliphatic hydrocarbon.[42] This latter reaction is effected rather readily by aluminum chloride. Boron fluoride, on the other hand, was found to be a catalyst for the alkylation reaction, although it had no effect on paraffins and did cause polymerization of olefins. It was necessary, though, to have present some finely divided metal, such as nickel, and either water or anhydrous hydrogen fluoride.

V. Grosse, U. S. P. 2,057,432, Oct. 13, 1936, to Universal Oil Products Co.; *Chem. Abs.*, 1936, 30, 8598.

[42] This reaction is called "auto-destructive alkylation." See Chapter 6.

Interactions of ethylene with isobutane, isopentane and 2,2,4-trimethylpentane and of isobutene and isobutane were effected in a high-pressure rotating autoclave of 800 cc. capacity (Fig. 140). The product in each run appeared to consist essentially of the expected paraffins of 2, 4, 6 or 8 more carbon atoms. Analysis was carried out by means of a Podbielniak column.[43] The gaseous reactants were weighed in small duraluminum autoclaves. Ethylene was introduced under a pressure of 20 kg. per sq. cm., and as this decreased because of the unsaturated hydrocarbon entering into combination with the other reactants, more was added. The results obtained in the experiments in which ethylene and isobutane were used are given in Table 127.

[a] In Experiments 1-5 Pyrex glass liners, and in Experiment 6 a nickel liner, were used.

It is apparent from these data (Exp. 4, 5 and 1) that an increase in the ratio of boron trifluoride to the available paraffin increases the rate of alkylation. The product depends upon the relative number of molecules of ethylene absorbed per molecule of butane. There is also formed a semi-solid mass composed of catalysts together with an organic complex which is apparently the real accelerator. It reacts readily with water to give a layer of unsaturated hydrocarbons and a solution containing nickel salts of hydroborofluoric acid.

The liquid product was water-white and after washing and drying was shown to contain neither aromatics nor olefins. This indicated that reaction had taken place between the paraffin and olefin.

Ipatieff, Komarewsky and Grosse[44] have pointed out that boron trifluoride also has a somewhat different reactivity from aluminum chloride in bringing about combination of cycloalkanes with olefins. As with alkanes, condensation is only effected at a tertiary carbon atom, and hence boron trifluoride causes interaction of ethylene with either methylcyclopentane or methylcyclohexane, but not with cyclopentane or cyclohexane. Union takes place at 20° to 30°C. and at ethylene pressures between 5 and 15 atmospheres. There appears to be some polymerization of the olefin and splitting of the ring simultaneously with the alkylation.

When aluminum and hydrogen chlorides were used as a catalyst, alkylation was effected fairly readily according to the general reaction:

$$C_mH_{2m} + C_nH_{2n} \xrightarrow{\text{catalyst}} (C_mH_{2m-1})(C_nH_{2n+1})$$

Frey and Hepp[45] report that the product secured from ethylene and propane, at 4500 lb. pressure and about 510°C., is a liquid pentane of which approximately two-thirds is isopentane and one-third *n*-pentane. Simultaneously, however, some hexanes and heptanes were also formed. The yield of products depended upon the proportion of reactants, varying from 7.2 per cent (result of reaction of a mixture of 4.7 per cent ethylene and 95.3 per cent propane) to 11.2 per cent (from olefin and paraffin, 8.9 and 91.1 per cent, respectively). Isobutane and the unsaturated hydrocarbon, at the temperature and pressure mentioned above, gave mainly 2,2-dimethylbutane and 2-methylheptane, together with some heptanes and octanes. It was also observed that the extent to which alkylation occurred was greater at high pressures (4500-4700 lbs.) than lower pressures (2500 lbs.) though the composition of the resulting liquids was but little affected. Frey and Hepp point out that the rate at which a tertiary hydrogen is replaced by an ethyl radical is greater than for a secondary hydrogen and much more rapid than for a primary hydrogen.

CONDENSATION OF OLEFINS WITH NAPHTHENES

The products from cyclohexane and ethylene would accordingly be mono- and higher ethylcyclohexanes. However, because of a rearrangement of ethylcyclohexanes, described by Grignard and Stratford[46] as occurring in the presence of aluminum chloride, *m*-dimethyl- and 1,2,4,5-tetramethylcyclohexane were actually obtained. These two substances were separated by dehydrogenation over a nickel-alumina catalyst and subsequent bromination. 2,4,5,6-Tetrabromo-1,3-dimethylbenzene so prepared melted at 243°C. The tetramethyl derivative was isolated and identified as the dibromide of the corresponding aromatic compound. Alkylation was believed to take place as indicated below.

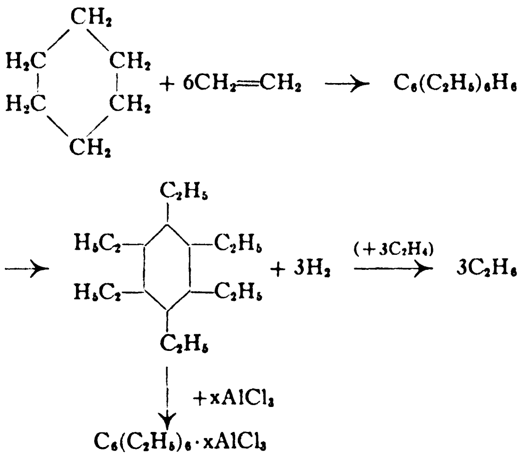
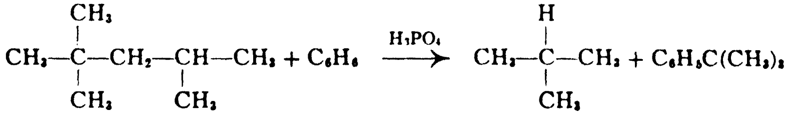
From the pasty reaction mass remaining after distillation of the volatile portion, it was possible to isolate a hydrocarbon (m.p. 147°C.) which was identified as hexaethylbenzene. This was assumed to be formed by intramolecular dehydrogenation of hexaethylcyclohexane. The hydrogen thus liberated was apparently taken up by ethylene since a small amount of ethane was found in the exit gases. This series of reactions may be represented by:



The molecular addition product of the benzene derivative and aluminum is known as a Gustavson complex.[47]

The interaction which takes place between cyclopropane and an aromatic hydrocarbon has been mentioned previously in this chapter. Grosse and Ipatieff[48] have also described an analogous combination between cyclopropane and isobutane in the presence of aluminum and hydrogen chlorides either at room temperature or at —30°C. At the lower temperature some cyclopropane remains unreacted. The product, however, consists largely of various heptanes.

In Chapter 6 the action of aluminum chloride on paraffins and aromatics at high temperatures has been discussed. In this reaction, which is called destructive alkylation, there is cracking of the paraffin and alkylation of the aromatic hydrocarbon. Ipatieff, Komarewsky and Pines[49] have observed that a similar reaction occurs when benzene is heated with either *n*-hexane or 2,2,4-trimethylpentane in the presence of phosphoric acid as a catalyst. In the latter instance alkylation of the aromatic hydrocarbon by olefins formed from the paraffin by action of phosphoric acid is believed to occur.



$$CH_3—\overset{CH_3}{\underset{CH_3}{C}}—CH_2—\underset{CH_3}{CH}—CH_3 + C_6H_6 \xrightarrow{H_3PO_4} CH_3—\overset{H}{\underset{CH_3}{C}}—CH_3 + C_6H_5C(CH_3)_3$$

$$2CH_3(CH_2)_4CH_3 + 2C_6H_6 \xrightarrow{H_3PO_4} C_3H_8 + C_2H_6 + C_6H_5CH(CH_3)_2 + C_6H_5—C_4H_9$$

The results of experiments on alkylation as well as the effect of heating any one of the hydrocarbons either alone or with phosphoric acid are given in Table 128.

[a] In Experiments 2, 6 and 7 the paraffin was *n*-hexane, in 1, 3, 4 and 5 it was 2,2,4-trimethylpentane, in 8 and 9 no paraffin was used. The capacity of the autoclave in which the reaction was carried out was 850 cc. The temperature was 450°C.

[b] Average molecular weight for paraffin was 30.

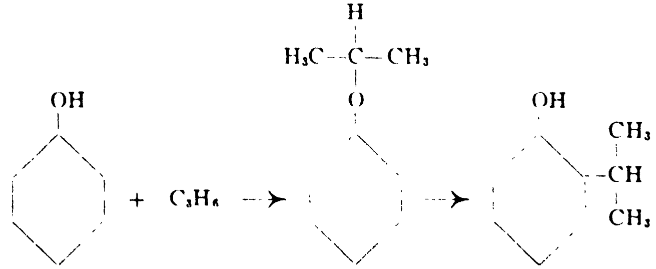
[c] Average molecular weight for paraffin was 34.

In Experiments 1 and 2 the liquid product contained *ter*-butyl- and isopropyl- benzene, respectively; in the others it was largely the original hydrocarbon. The results given above show that there is a destructive alkylation which takes place in the presence of phosphoric acid, but not at all in the absence of a catalyst. There is apparently only slight cracking of the paraffin induced by the acid, since the gaseous products do not differ greatly whether the hydrocarbon is heated alone or with the catalyst.

Another catalyst which has been used to effect the condensation of ethylene with a naphthenic hydrocarbon oil is molybdenum oxide.[50] The product may be employed as a motor fuel.

CONDENSATION OF OLEFINS WITH PHENOLS

The condensation of alkenes with phenols is similar in some respects to that with aromatic hydrocarbons. Reaction is catalyzed by anhydrous metallic halides, sulphuric acid, phosphoric acid and certain activated clays or bleaching earths. Sowa, Hinton and Nieuwland[51] suggested that interaction, with propene, for example, takes place in the following manner:



---

[50] M. P. Appleby, C. Cockram, British P. 415,792, 1934, to Imperial Chemical Industries, Ltd.; *J. Inst. Pet. Tech.*, 1934, **20**, 581A; *Chem. Abs.*, 1935, **29**, 918; *Brit. Chem. Abs.* **B**, 1934, 952. French P. 768,166, 1934, to Imperial Chemical Industries, Ltd.; *Chem. Abs.*, 1935, **29**, 580.

[51] F. J. Sowa, H. D. Hinton and J. A. Nieuwland, *J.A.C.S.*, 1932, **54**, 3694; *Brit. Chem. Abs.* **A**, 1932, 1125; *Chem. Abs.*, 1932, **26**, 5294.

The rearrangement (indicated above) of the intermediate compound was studied more extensively by the same workers[52] and was confirmed for several phenyl and cresyl ethers. It is comparable to the shifting of the acyl group of a phenyl ester to form a hydroxy phenyl ketone which occurs on treating the ester with aluminum chloride below 75°C.[53]

One of the most important catalytic agents for the alkylation of phenols is sulphuric acid. Thus, Evans and Edlund[54] observed that a tertiary olefin will react with phenol at 25°C. in the presence of sulphuric acid. A germicidal product has been prepared by the condensation of a phenol and a cracked gasoline fraction in the presence of strong sulphuric acid.[55] The product consists essentially of mixed alkyl phenols in which the side-chains have more than 4 carbon atoms. Compounds synthesized in this manner have been suggested also as antioxidants, particularly for the prevention of gum-formation in gasoline, for the stabilization of lubricating and transformer oils and as anti-aging agents for rubber.[56] Methods for preparing *ter*-amyl phenol[57] have been suggested by Lee and Clark[58] and by Thomas[59] in which phenol is treated with a solution of isopentene in sulphuric acid. Such a procedure is also applicable with an aliphatic or cyclic olefin in 90 per cent or stronger acid. The alkylated product is isolated by diluting the reaction mixture with water. If sulphonation of the phenol has taken place it is necessary to effect hydrolysis of the sulpho group by boiling with dilute acid or distillation with superheated steam.[60] *p-ter*-Amyl phenol is advocated as a plasticizing agent for lacquers containing ethyl cellulose and a compatible phenol-formaldehyde resin.[60a]

Niederl[61] reported the alkylation of polyphenols or their monoethers with diisobutylene in the presence of sulphuric acid. The reactants may be dissolved in acetic acid. The compounds thus secured are 1,1,3,3-tetramethylbutyl derivatives of the hydroxy-compound employed as one of the reacting substances. Although diisobutylene is a mixture of two isomeric trimethylpentenes, only one product is obtained.[62] Interaction, therefore, may be represented as indicated below.

Triisobutylene may be substituted for the dimer.[63] In this instance, however, since the former material contains many isomers, of which five have been isolated, it is better to separate it into several fractions and react these individually with phenolic bodies. The polymeric isobutene derivatives so prepared are said to be applicable as antiseptic, fungicidal or bactericidal agents, as intermediates in the manufacture of dyes or as artificial tanning or wetting-out compounds.[64] Bruson and Covert[65] suggest that these substances be hydrogenated to the corresponding hydroxy cycloparaffins. The latter, because of their low boiling points and vapor pressures, are recommended as plasticizers for coating and molding compositions and as lubricants for textile fibers or fine mechanisms, e.g., watches. They may also be oxidized with nitric acid to *ter*-alkyl adipic acids.

Ipatieff[66] proposed that combination between phenols or polyphenols and olefins (such as ethylene or propene) be carried out employing phosphoric acid as the contact agent. Chichibabin[67] observed that the methyl ether of a cresol, such as *p*-methoxy toluene, will react with isobutene in the presence of either phosphoric or sulphuric acid. On the other hand, Vonderwahl[68] has suggested the preparation of 4-*ter*-butyl-3-methyl-phenyl methyl ether by reacting *m*-tolyl methyl ether with isobutene using anhydrous aluminum, zinc, ferric or antimony chloride as the catalyst. Another halide which has been employed in the alkylation of phenols is boron trifluoride. For example, heating tar phenol, ethylene, boron fluoride and hydrogen chloride in an autoclave is said to form the phenol ethyl ether.[69]

Various other substances such as alumina, aluminum phosphate, mixed aluminum and magnesium silicates, and kieselguhr as well as zinc chloride have been suggested as catalysts for the preparation of isopropylcresols from propene and the methyl phenol.[70] The reaction may be carried out in liquid or vapor phase. In this way it was found possible to make thymol (3-hydroxy-4-isopropyltoluene) and its isomers, including 4-hydroxy-2-isopropyltoluene (m.p. 37°C.) and 3-hydroxy-2-isopropyltoluene (m.p. 69°C.). Siliceous catalysts, such as fuller's earth or clay, have been employed by Britton and Perkins[71] to effect the condensation of a phenol and cyclohexene at 100° to 350°C., and 1 atmosphere pressure, to cyclohexylphenol.

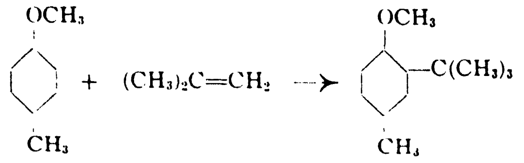
In an analogous manner, Schoeller and Jordan[72] reacted a phenol and propene at 135 to 200°C.

Alkylation of phenyl ethers has been accomplished by Dubinin[73] using 5 per cent of aluminum chloride dissolved in the ether as a catalyst. For example, isobutene and *p*-methoxytoluene furnished 1-methyl-4-methoxy-3-*ter*-butylbenzene.



The quantity of product obtained corresponded to a 71 per cent yield. The *ter*-butyl derivative of *o*-methoxytoluene was also synthesized in like manner, the yield in this instance amounting to 58 per cent. The product from 1,3-dimethoxybenzene (b.p. 120-122°C. at 11 mm.) was also made in a 71 per cent yield and was shown to be probably 4-*ter*-butyl-1,3-dimethoxybenzene, together with some 4,6-di-*ter*-butyl-1,3-dimethoxybenzene.

The interaction of 3-methylpentene with phenolic substances leads, according to Koenigs and Carl,[74] to the formation of alkylated derivatives. For example, 4-*ter*-amyl-2-methyl-6-isopropylphenol was obtained from thymol and isoamylene. A similar reaction could be carried out using styrene (phenylethylene) and a phenol, the product being, in this case, a hydrated stilbene.

An extension of this condensation applies to the addition of alcohols[75] or glycols[76] to olefins with the formation of *ter*-alkyl ethers. The reaction is catalyzed by sulphuric, phosphoric or aromatic sulphonic acids, metallic chlorides, for example, those of zinc, aluminum, or iron, or non-metallic halides, e.g., boron trifluoride or phosphorus oxychloride. Other substances which exert an accelerating effect are charcoal, kaolin, silica gel or kieselguhr. As an example,[77] methyl sulphuric acid (from the corresponding alcohol and acid and containing 55 per cent free acid) was treated for 2 hours at 95 to 100°C. with a butane-butene fraction (95 per cent olefin) of cracking gas. The mixture was cooled and allowed to stratify. The

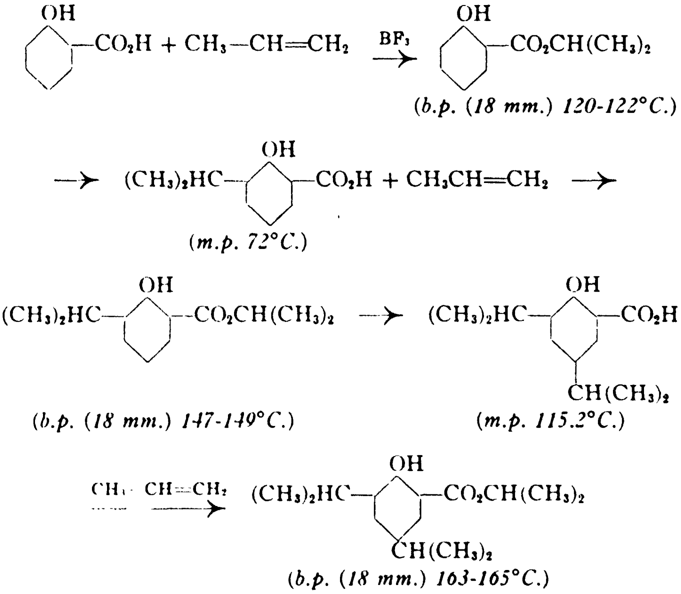
upper layer was then distilled, in the presence of alkali, to recover methyl-*sec*-butyl ether (boiling at 61°C.). The lower layer was diluted with methyl alcohol and subjected to the action of butene.

A softening agent for cellulose esters may be obtained by heating isopropanol with isobutene and concentrated sulphuric acid.[77a] When interaction is carried out at 95°C., isopropyl-*ter*-butyl ether is formed. Similar compounds, applicable for the same use, may be secured by treatment of other alcohols with olefins, provided the latter are capable of yielding tertiary alcohols when hydrated.

A number of ethers synthesized from olefins and alcohols are listed in Table 129.

CONDENSATION OF OLEFINS WITH ACIDS

Direct union of olefins and carboxylic acids to give esters has been previously discussed.[78] However, those reactions involving hydroxy aromatic acids are considered here since in many respects they resemble interaction between unsaturated hydrocarbons and phenols. Croxall, Sowa and Nieuwland[79] studied alkylation of salicylic acid with propene in the presence of boron trifluoride. The products were 3-mono- and 3,5-di-isopropyl-2-hydroxy-benzoic acids, their isopropyl esters and isopropyl salicylate. Combination was considered to take place with the formation of isopropyl salicylate, which underwent rearrangement followed by esterification and further reactions.



Propene (under a pressure of 8 to 10 cm. of mercury) was conducted into a suspension of 35 g. of salicylic acid in 210 g. of heptane with which 4 g. of boron trifluoride had been incorporated. A few grams more of boron fluoride were added during the reaction. After three days 1.25 moles of propene had been absorbed. The reaction was then stopped and the products mentioned above isolated. No alkoxylated derivatives were observed which was thought to be due to the greater

tendency of boron trifluoride to condense with the carboxy or carbalkoxy group than the phenolic group. The postulated mechanism of rearrangement was supported by isomerization of isopropyl salicylate under the experimental conditions employed.

In addition to the reaction of propene with *o*-hydroxybenzoic acid, those with *m*- and *p*-hydroxybenzoic acids have also been investigated.[80] In the latter instances, isopropyl ethers of hydroxybenzoic and hydroxyisopropylbenzoic acid and their esters were isolated. It was suggested that the formation of 3-isopropoxybenzoic acid and isopropyl *m*-hydroxy benzoate occurred simultaneously, whereas 4-isopropoxybenzoic acid was formed to the exclusion of isopropyl *p*-hydroxy benzoate. Interactions occurring when *m*-hydroxybenzoic acid was used are indicated on page 608.

The mechanism of the intermediate step was not completely established, for both isopropyl *m*-hydroxy benzoate and 3-isopropoxybenzoic acid rearranged to give the same product (3-hydroxy-4-isopropylbenzoic acid; m.p. 138-140°C.) under the experimental conditions.

Reaction between *p*-hydroxybenzoic acid and propene may be represented by the equations given on page 610.

The exact sequence of steps is uncertain, because of three possible courses for the reaction, viz., rearrangement of either isopropyl group or direct alkylation of the ring. It was considered that migration of the oxyisopropyl group was most probable since *p*-isopropoxybenzoic acid rearranges for the most part to 4-hydroxy-3-isopropylbenzoic acid.

CONDENSATION OF ALKENES WITH ACID HALIDES

Addition of acid chlorides to unsaturated hydrocarbons is a fairly general reaction which has prompted study by many investigators.[81] The reaction occurs, for example, with chlorosulphonic acid which unites with aryl ethylenes, e.g., styrene, safrole, coumarone and indene, to give chlorosulphonic acids in which the chlorine may be replaced by other groups, such as hydroxyl.[82] Phosgene, which may be considered either as the chloride of chloroformic acid or the dichloride of carbonic acid, is said to combine with ethylene in some solvents. Varshavskii and Doroganyevskaya[83] have shown that no 2-chloropropionyl chloride is formed in the presence of aluminum chloride when either toluene or carbon tetrachloride is the liquid medium. In the former, however, reaction tended toward that of the conventional Friedel-Crafts type. On the other hand, with carbon tetrachloride as a solvent the product apparently consisted of polymers formed by the action of aluminum chloride on the olefin. These results were corroborated by Klebanskii and Chevuichalova,[84] who observed, furthermore, that chlorobenzene was also unsatisfactory as a solvent. The optimum conditions were found to be cooling and stirring of a solution of 0.5 g. aluminum chloride per mole of carbon disulphide in which phosgene and ethylene reacted. The main product was believed to be 2-chloropropionyl chloride, although this substance could not be isolated directly. The reaction mixture was decomposed by addition of absolute alcohol, and the esters of chloro-

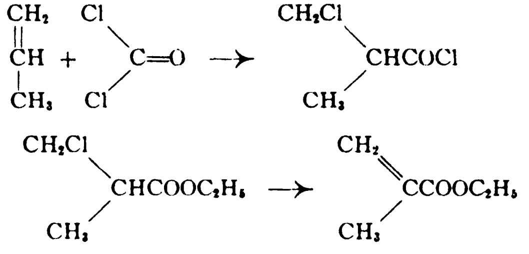
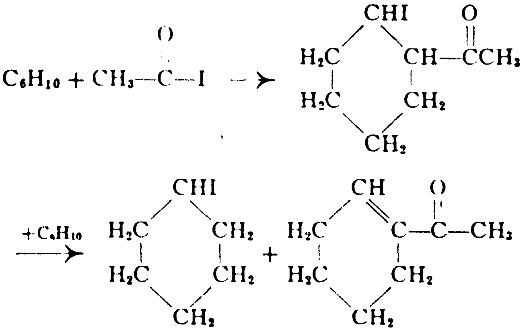
propionic acid then separated from polymerized ethylene. No better results were obtained when zinc chloride was used in place of aluminum chloride.

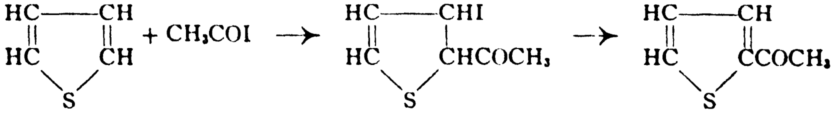
Reid[85] also interacts phosgene, in the presence of aluminum chloride, with propene to give a β-chloro acid chloride. Esters are then formed by the addition of an alcohol such as ethanol, propanol, ethanediol or propantriol. By removal of hydrogen chloride from the latter, esters of methacrylic acid are obtained.



Combination of chlorides of aliphatic organic acids with ethylenic compounds should lead to the synthesis of 2-chloroketones. Frolich and Wiezevich[86] have made chloroethyl methyl ketone from ethylene and acetyl chloride by heating them to a temperature of at least 100°C. under pressure in the presence of charcoal. Stevens[87] has studied the action of acetyl iodide on unsaturated hydrocarbons. He observed that the 2-iodoketones formed were very reactive and lost hydrogen iodide readily. For example, cyclohexene and acetyl iodide gave iodohexahydroacetophenone which then yielded tetrahydroacetophenone and cyclohexyl iodide.[88]



When thiophene was treated with the acid iodide some acetothienone[89] was isolated from the reaction product. Its formation can be indicated by:



In addition large quantities of iodine and tarry material were obtained. These are probably due to loss of iodine from a diiodo derivative and polymerization of the resulting diketone. Divinyl ether and furan also reacted vigorously with acetyl iodide.

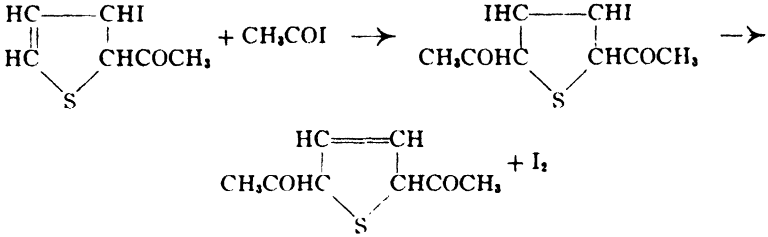
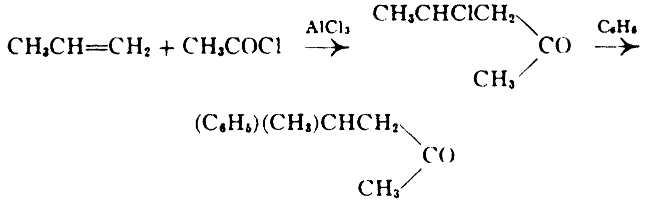
[87] P. G. Stevens, *J.A.C.S.*, 1934, **56**, 450; *Chem. Abs.*, 1934, **28**, 1661; *Brit. Chem. Abs.* **A**, 1934, 391.

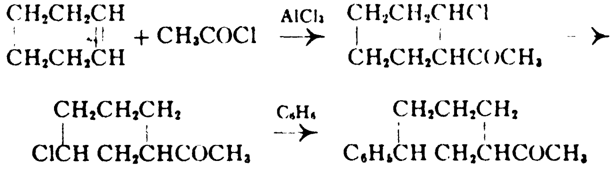
[88] *Cf.* the results of E. L. Gustus and P. G. Stevens (*J.A.C.S.*, 1933, **55**, 378; *Chem. Abs.*, 1933, **27**, 956) who report that aliphatic ethers react with acetyl iodide to give an addition compound which in turn decomposes to an alkyl iodide and alkyl acetate.

[89] This compound may be prepared also from thiophene and acetyl chloride. G. Stadnikoff and W. Rodowsky, *Ber.*, 1928, **61**, 268; *Chem. Abs.*, 1928, **22**, 1774; *Brit. Chem. Abs.* **B**, 1928, 427.



The condensation of acetyl chlorides with cyclohexene, cyclopentene, cyclohexene carboxylic acid, ethylene, propene, butene-1 and butene-2, and hept-3-en-2-one has been studied by Nenitzescu and Gavat.[90] It was found that in the presence of aluminum chloride the reaction led to the formation of a chloroketone in which the chlorine atom had migrated to a remote carbon atom of the condensation product. However, the wandering would not go so far as a terminal methyl group. Thus, cyclohexene gave 4-chlorohexahydroacetophenone, and propene and acetyl chloride, followed by treatment with benzene, gave 2-phenylpentanone-4.



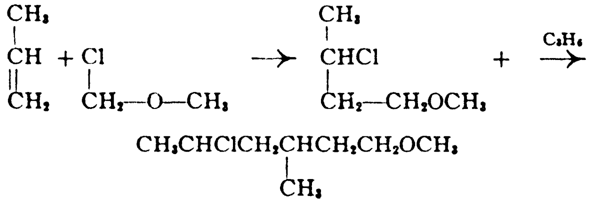


The reactions were carried out using carbon disulphide as a liquid medium. For example, 30 liters of butene-1 (gas) were slowly introduced into a solution of 133 g. aluminum chloride and 78 g. acetyl chloride in 150 cc. carbon disulphide maintained at —14°C. After two layers had separated, the upper was removed and added to 300 cc. of benzene and 30 g. aluminum chloride. The mixture was refluxed at 40°C. for 4 hours and the product (identified as 5-phenylhexanone-2, b.p. 122-125°C. at 9 mm.) separated by distillation. The yield was 19 g. The results obtained in these experiments showed that the migration of the chlorine atom was fairly general. With alkenes having more than 4 carbon atoms in a chain, there was so much polymerization under the experimental conditions that the resulting ketones could not be isolated. Those of higher molecular weights (such as 6-phenylheptanone-2) were made by condensation of the corresponding alk-3-en-2-ones (from an aldehyde and acetone) with benzene. Rearrangement of the phenyl group was shown to take place by synthesizing 5-phenylhexanoic acid and passing this (with acetic acid) over thorium oxide at 400°C. The resulting ketone (6-phenylheptanone-2) was identical with that previously mentioned.

[90] C. D. Nenitzescu and I. Gavat, *Ann.*, 1935, 519, 260; *Chem. Abs.*, 1935, 29, 7279; *Brit. Chem. Abs.* A, 1935, 1368.

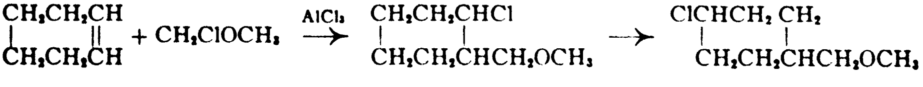
Bergs[91] interacted cyclohexene and phenylacetyl chloride in carbon disulphide solution in the presence of stannic chloride. After treatment of the product with diethyl aniline he obtained 1-phenylacetylcyclohexene-1. Nenitzescu and Cioranescu[92] found that when cyclohexene was the solvent and maintained at low temperatures union between an olefin and an acid chloride proceeded normally to give a chloroketone. However, on raising the temperature, the chlorine atom was eliminated. This was attributed to interaction with hydrogen liberated by intracondensation of solvent molecules, e.g., cyclohexane, to furnish dicyclohexane and hydrogen. As an illustration of this mode of procedure, 68 g. of cyclopentene and 78 g. of acetyl chloride were dissolved in 200 cc. of cyclohexane, and to the solution, maintained at —15°C., were slowly added 266 g. of aluminum chloride. The temperature was then increased to 70°C. and kept there until the evolution of hydrogen chloride ceased. The product in this instance was not methyl-chlorocyclopentyl ketone but methyl cyclopentyl ketone.

Somewhat related to an acid halide, at least insofar as the lability of the halogen atom is concerned, are α-haloethers such as chlorodimethyl ether. Scott[93] observed that these α-halogenated ethers condense with olefinic substances to give γ-haloethers. Reaction is catalyzed by readily hydrolyzable metal halides and may be carried out under increased pressure. For example, chloromethyl ether and propene condense under 150 lbs. per sq. in. at 50 to 70°C. in the presence of bismuth chloride to give methyl 3-chlorobutyl and methyl 5-chloro-3-methylhexyl ethers, the latter as a secondary product.



$$\begin{array}{l} CH_3 \\ | \\ CH \\ \| \\ CH_2 \end{array} + \begin{array}{l} Cl \\ | \\ CH_2{-}O{-}CH_3 \end{array} \longrightarrow \begin{array}{l} CH_3 \\ | \\ CHCl \\ | \\ CH_2{-}CH_2OCH_3 \end{array} + \xrightarrow{C_3H_6} \begin{array}{l} CH_3CHClCH_2CHCH_2CH_2OCH_3 \\ \qquad\qquad\quad | \\ \qquad\qquad\quad CH_3 \end{array}$$

Nenitzescu and Przemetzki[94] found that cyclohexene and chloromethyl ether condense in a medium of carbon disulphide, in the presence of zinc chloride, to give 4-chloro-1-methoxymethyl cyclohexene. The 2-chloro derivative was probably formed as an intermediate. This shift of the chlorine atom is in accordance with the theory of migration previously advanced in connection with the addition of acid chlorides to olefin, that is, that the chlorine atom migrates to a remote carbon atom of the condensation product, though not so far as to a terminal methyl group.



$$\begin{array}{l} CH_2CH_2CH \\ | \qquad\quad \| \\ CH_2CH_2CH \end{array} + CH_2ClOCH_3 \xrightarrow{AlCl_3} \begin{array}{l} CH_2CH_2CHCl \\ | \qquad\quad | \\ CH_2CH_2CHCH_2OCH_3 \end{array} \longrightarrow \begin{array}{l} ClCHCH_2\,CH_2 \\ | \qquad\quad | \\ CH_2CH_2CHCH_2OCH_3 \end{array}$$

The structure of the methylmethoxy compound was further substantiated by treating it with benzene to secure 4-phenyl-1-methylmethoxy cyclohexane and dehydrogenating the latter to the corresponding aromatic which in turn was oxidized to *p*-phenylbenzoic acid.

A somewhat analogous reaction to that of olefins and chloroethers is the union of unsaturated hydrocarbons and chlorinated esters. For example, methyl acetate is halogenated and the resulting compound then condensed with ethylene, using aluminum chloride or boron trifluoride as catalyst, to yield the corresponding halogenated ester.[95] Dehalogenation of compounds of the latter type may be accomplished by treatment with hydrogen at 150 to 300°C. and pressures of 100 lbs. per sq. in. or higher.

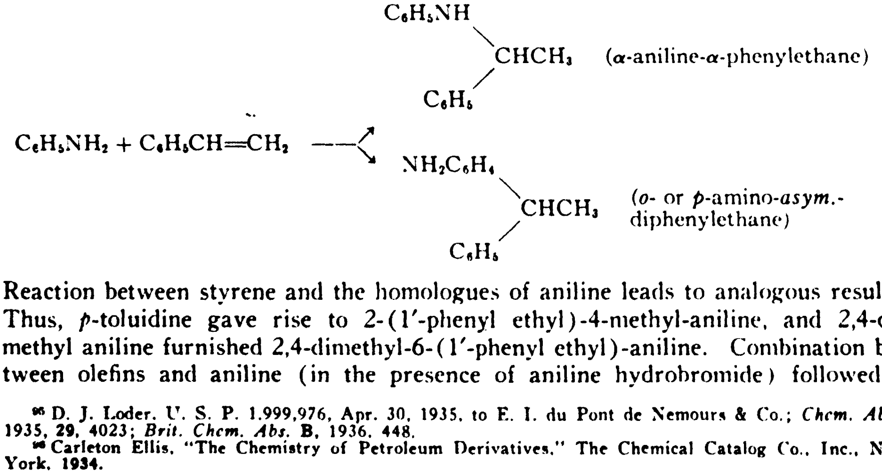
CONDENSATION OF OLEFINS WITH AMMONIA AND AMINES

Interaction between an olefin and ammonia (or a primary or secondary amine) to give an amine has not received very great attention.[96] According to Sun[97] activation energy calculations indicate that combination will not occur readily and that a primary amine will decompose into a secondary amine rather than into hydrazine and ethylene. Gasoline fractions containing amino bodies may be secured by having ammonia present during cracking operations[98] or by treating the cracked vapors with chlorine and this nitrogen compound under pressure and at temperatures of 150° to 315°C.[99] In place of olefins, substances giving rise to them may be employed in the preparation of secondary amines.[100] For example, an arylamine (e.g., aniline, *o*- or *p*-toluidine) and cyclohexanol are conducted, under pressure and at temperatures of 200° to 270°C., over a non-metallic catalyst. Hydrated silicates, or the oxides of thorium, aluminum or tungsten may be employed. Hickinbottom has investigated the addition of arylamines to alkenes[101] and styrene.[102] There was a tendency in either case for the reaction to give two types of product; (1) a secondary alkyl, or substituted, phenylamine, and (2) a primary substituted arylamine. Thus, from aniline and styrene at 200 to 240°C., using aniline hydrochloride as a catalyst, were obtained α-anilino-α-phenylethane as well as *o*- and *p*-amino-*asym.*-diphenylethane.



C₆H₅NH
CHCH₃
(α-aniline-α-phenylethane)
C₆H₅
C₆H₅NH₂ + C₆H₅CH=CH₂
NH₂C₆H₄
CHCH₃
(o- or p-amino-asym.-diphenylethane)
C₆H₅

Reaction between styrene and the homologues of aniline leads to analogous results. Thus, *p*-toluidine gave rise to 2-(1′-phenyl ethyl)-4-methyl-aniline, and 2,4-dimethyl aniline furnished 2,4-dimethyl-6-(1′-phenyl ethyl)-aniline. Combination between olefins and aniline (in the presence of aniline hydrobromide) followed a somewhat similar course. For example, 6 g. of 2-methylbutene-2, 30 g. of aniline and 3 g. of aniline hydrobromide were heated in sealed tubes at 230 to 250°C. for 6.5 hours. The product was 3.7 g. *p*-amino-*ter*-amylbenzene, 0.57 g. N-*ter*-amylaniline and 2.05 g. diphenylamine. The latter was probably formed directly from the aniline.

The formation of an alkyl aniline is favored by lowering the proportion of aniline hydrobromide.[103] Experiments were carried out using 3-methyl- and 3-ethylpentene-2 and octene. It was found that the structure of the olefin played an important part in determining whether amino- or ring-alkylation occurred. Although isoamylene gave a preponderance of the products of the latter type, the reverse was true of octene (from dehydration of *sec*-octanol).

In addition to the investigations of Hickinbottom, the work reported by Pinck and Hilbert[104] on the addition of ammonia and ethylamine to the unsaturated bond of dibiphenylene ethylene deserves mention. It was observed that heating 1 g. of the hydrocarbon and 15 cc. of liquid ammonia in a sealed tube at 65°C. for 3 weeks gave 0.5 g. of an unidentified substance (m.p. 300°C.) and 0.4 g. of 9-iminofluorene. In place of ammonia, methyl-, ethyl and benzylamine were also employed. The main product when ethylamine was one of the reactants was 1-ethylaminodiphenylene ethane. Dissociation of the latter was brought about by heating 2 g. of the substance with 20 c.c. of absolute ethanol for 10 days at 100°C. In addition to fluorene and 9-ethyliminofluorene, some fluorenone was formed, probably due to hydrolysis of the imino derivative.

Chapter 25

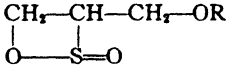
Miscellaneous Reactions of Olefins (II)

The preceding chapter was devoted to a discussion of the miscellaneous reactions of olefins with a number of organic reagents, involving principally condensations with paraffins (the so-called alkylation process), aromatics, phenols, acid chlorides, amines and ammonia. The present chapter will deal with the action of various inorganic substances, such as the oxides and halides of sulphur and nitrogen, carbon monoxide, and metallic salts and of aldehydes on the simpler unsaturated hydrocarbons.

Although most of the reactions involved are of interest only from the standpoint of general properties, several also have attained technical importance, or may hold potential commercial possibilities. One instance of the former is the use of mercuric acetate and thiocyanogen in analytical procedures.[1] The latter type may be represented by the production of acids by the union of carbon monoxide and steam with olefins, or the production of synthetic resins (by condensation of unsaturates with aldehydes) as will be discussed in due course in this chapter.

REACTION OF SULPHUR DIOXIDE AND SULPHITES WITH OLEFINS

Sulphur dioxide and its various derivatives, i.e., sulphurous acid and its salts, combine with olefins under many conditions.[2] Contrary to the results obtained by the action of sulphuric acid (which leads to the formation of sulphates)[3] the products formed from sulphurous acid and sulphites are usually sulphonic acids, or condensed sulphones. One of the earliest reports of the reaction of an olefinic substance and sulphur dioxide was made by Solonina.[4] He found that allyl ethers reacted in benzene solution to give sulphur-containing compounds which he represented by the formula:



Subsequently, the reaction of sulphur dioxide and unsaturated hydrocarbons was investigated by various workers. Thus from this reagent and cyclohexene, Frederick, Cogan and Marvel[5] have isolated a polymolecular sulphone with a molecular weight of about 6000, which they represented by the probable formula:

[2] For example, the formation of disulpho-propionic and butyric acid has been investigated by H. J. Backer and A. E. Beute. *Rec. trav. chim.*, 1935, 54, 601, 621; *Chem. Abs.*, 1936, 30, 3776. 3777; *Brit. Chem. Abs.* A, 1935, 1106, 1107.

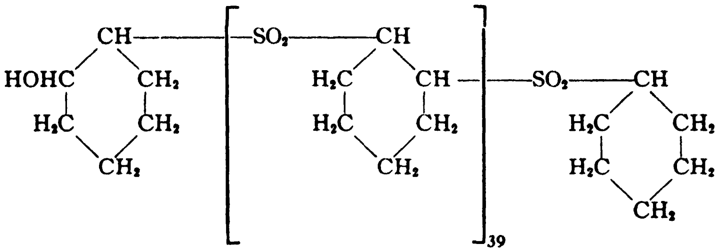
[4] V. Solonina, *J. Russ. Phys.-Chem. Soc.*, 1898, 30, 826; *J.C.S.*, 1899, 76, 681; *Chem. Zentr.*, 1899, 1, 248.

[5] D. S. Frederick, H. D. Cogan, and C. S. Marvel, *J.A.C.S.*, 1934, 56, 1815; *Chem. Abs.*, 1934, 28, 6118; *J. Inst. Pet. Tech.*, 1934, 20, 522A; *Brit. Chem. Abs.* A, 1934, 1095.



This substance was a white amorphous solid which softened and decomposed above 200°C. Although quite soluble in chloroform and tetrachloroethane, it was only slightly soluble in most other solvents. Heating to 250°C. with 90 per cent potassium hydroxide solution caused decomposition, largely to cyclohexene and octahydrobiphenyl.

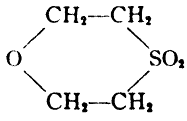
A somewhat similar transformation, which is catalyzed by peroxides, has been reported by Staudinger and Ritzenthaler.[6] They found that ethylene and propene combine with sulphur dioxide to form high molecular weight compounds. In the case of ethylene, only ether peroxides served as catalysts, whereas in the other instances, various other higher oxides (for example, ozone and benzoic peroxide) were effective accelerators. The product from propene was believed to be very highly polymeric (molecular weight of 390,000 in one case) because of viscosity measurements of its solution in sulphuric and nitric acid. For ethylene, the structure might be represented either as sulphones:

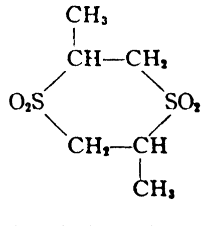
$$\ldots\ldots CH_2{-}CH_2SO_2{-}CH_2{-}CH_2{-}SO_2\ldots\ldots$$

or as sulphinic esters:

$$\ldots\ldots CH_2{-}CH_2{-}O{-}SO{-}CH_2{-}CH_2{-}O{-}SO\ldots\ldots$$

However, the stability of the substance toward oxidation and bromination supports the former structure. Treatment with barium hydroxide resulted in mixtures of barium sulphinates and (from polyethylene- and propene-sulphone, respectively), the compounds:





These results have been substantiated by other independent investigations. Hunt and Marvel[7] obtained a much lower value for the molecular weight of polypropenesulphone (about 2000), but later work by Ryden and Marvel[8] using trichloroacetyl derivatives and anilides and analyzing for chlorine gave a molecular weight between 100,000 and 200,000. The researches of Hunt and Marvel largely confirmed the structure proposed by Staudinger and Ritzenthaler. The former work-

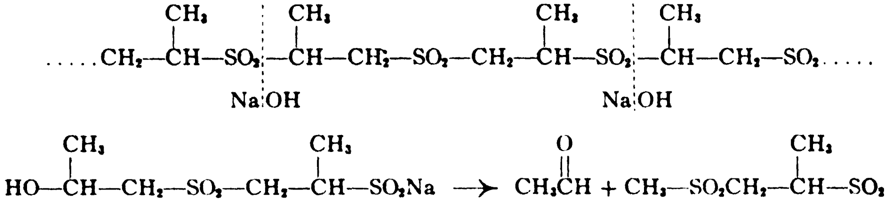
[7] M. Hunt and C. S. Marvel, *J.A.C.S.*, 1935, 57, 1691; *Chem. Abs.*, 1935, 29, 7276; *Brit. Chem. Abs.* A, 1935, 1349.

[8] L. L. Ryden and C. S. Marvel, *J.A.C.S.*, 1935, 57, 2311; *Brit. Chem. Abs.* A, 1936, 186; *Chem. Abs.*, 1936, 30, 75.

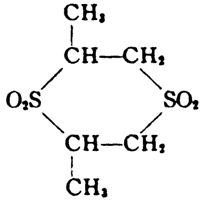
ers tried cleaving the polypropene sulphone by boiling with 10 per cent sodium hydroxide, and obtained two products. The first was a red resinous substance which was identified as the resin formed by boiling acetaldehyde with alkali. This indicated that 2 out of every 6 atoms of carbon in the polysulphone were converted to acetaldehyde on hydrolysis. The second product was shown by synthesis to be the sodium salt of 2-methyl sulphonyl-1-methylethane-1-sulphonic acid. The formation of these products was explained by the equation:



$$\ldots\ldots CH_2-\overset{CH_3}{\overset{|}{C}}H-SO_2\underset{Na\vdots OH}{\vdots}-\overset{CH_3}{\overset{|}{C}}H-CH_2-SO_2-CH_2-\overset{CH_3}{\overset{|}{C}}H-SO_2\underset{Na\vdots OH}{\vdots}-\overset{CH_3}{\overset{|}{C}}H-CH_2-SO_2\ldots\ldots$$

$$HO-\overset{CH_3}{\overset{|}{C}}H-CH_2-SO_2-CH_2-\overset{CH_3}{\overset{|}{C}}H-SO_3Na \longrightarrow CH_3\overset{O}{\overset{\|}{C}}H + CH_3-SO_2CH_2-\overset{CH_3}{\overset{|}{C}}H-SO_3Na$$

The structure assigned by Hunt and Marvel to the product of mild hydrolysis of the polysulphone was somewhat different from the arrangement proposed earlier[8a] in that both methyl groups were on the carbon atoms attached to the same sulphone group.



The combination of sulphur dioxide with methylpropene, pentene-1, and -2, nonene-1, 3-cyclohexylpropene and 3-methylcyclohexene results in the formation of polysulphones, according to Ryden and Marvel.[9] However, many other olefinic compounds, both hydrocarbons and more complex substances, failed to react under the experimental conditions.[10]

Fitch[11] has proposed to make a resinous material by treating a mixture of olefins, (from which unsymmetrical, di-substituted ethylenes have been removed) with sulphur dioxide in the presence of diluents.

Vinyl sulphones and sodium, potassium or calcium bisulphites react in aqueous or alcoholic solution at 100°C. to give β-sulphoethylsulphones:[12] $R-SO_2-CH_2CH_2-SO_3H$. *p*-Tolyl and 2-naphthyl-β-sulphoethylsulphone and *m*-phenylene di(β-sulphoethyl)disulphone have been prepared in this manner.

REACTIONS OF SULPHUR CHLORIDES WITH OLEFINS

Under different conditions, the products of the reaction between sulphur chlorides and unsaturated hydrocarbons may vary considerably in properties. For example, by treating ethylene with sulphur chloride at 50 to 60°C., and then heating the product with sodium polysulphide (Na_2S_5), it is possible to prepare a resistant resin-like material.[13] As is well known,[13a] mixing ethylene with sulphur monochloride at temperatures up to about 70°C. results in the formation of 2,2′-dichlorodiethyl sulphide, or mustard gas (yperite), which first served in chemical warfare during the World War. In connection with this use, mention may be made of the methods employed in detecting this substance in the air.[14] A reaction between mustard gas and bleaching powder, which was described by Stampe and Schröter,[15] leads to the formation of white crystals of unestablished identity. The air to be tested, and air which has been passed over or through bleaching powder, are led into a container. If dichlorodiethyl sulphide is present, white crystals are deposited on the walls of the reaction vessel. Another method which has been suggested[16] consists of passing the gas through a solution containing either 0.1 per cent auric chloride or 0.05 per cent palladous chloride. Mustard gas, if present, causes a yellow colloidal turbidity, and when there in high concentrations, gives reddish-yellow oily droplets. This test is said not to be affected by other chemical warfare agents.

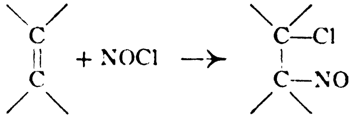
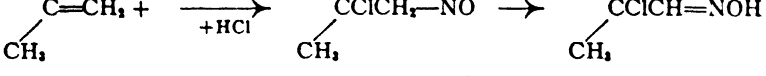
REACTIONS BETWEEN INORGANIC NITROGEN DERIVATIVES AND OLEFINS

The addition of nitrosyl chloride to unsaturates is somewhat analogous to the reactions occurring with other acid chlorides, as mentioned in Chapter 24. The resultants in this case are nitrosochlorides, formed according to the scheme:



The transformation may be effected by treating a solution of the olefinic substance with ethyl nitrite and hydrogen chloride in an anhydrous medium at low temperatures (0°C.). In this way, Cohen and Cook[17] succeeded in synthesizing 2(2′-phenyl)-ethyl-cyclohex-2-en-1-one from 1-(2′-phenyl)-ethylcyclohexene-1 with the intermediate formation of the nitrosochloride, and ketone oxime. The formation of the oxime was effected by boiling the nitrosochloride in pyridine.

Draw and Head[18] have employed a similar reaction in the production of isobutene diamine (1,2-diamino-2-methylpropane) from isobutene. The oxime form of the nitrosochloride was obtained as a white solid (m.p., 104°C.):



The chlorine was replaced by treatment with alcoholic ammonia, and the oxime reduced to an amino group with sodium amalgam and alcohol in acid solution.

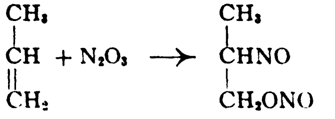
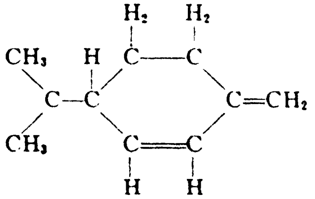
The reactions which take place between olefins and the oxides of nitrogen produce several different types of compounds. The introduction of nitrogen trioxide (the anhydride of nitrous acid) leads to the formation of a nitrosite. Thus Dem'yanov[19] has prepared propene nitrosite by the simultaneous passage of propene and nitrogen trioxide into ether:



$$\begin{array}{l} CH_3 \\ | \\ CH \\ \| \\ CH_2 \end{array} + N_2O_3 \longrightarrow \begin{array}{l} CH_3 \\ | \\ CHNO \\ | \\ CH_2ONO \end{array}$$

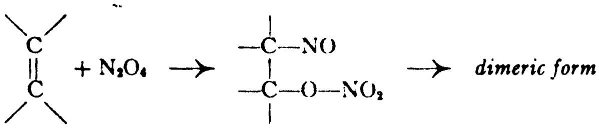
propene nitrosite

The nitrosites are usually bluish liquids which polymerize to give colorless bisnitrosites. By analogous procedures, the nitrosites of butene-1,[20] 2-methylpropene[21] and 2-methylbutene-2[22] have been prepared. If an excess of oxide is used there is said to be danger of the formation of a nitrosate. Gaponenkov[23] synthesized the nitrosites of certain of the terpenes, such as β-phellandrene, by the action of acetic acid on sodium nitrite in the presence of a solution of the hydrocarbon in a light petroleum ether and ethyl ether solvent.[24]



β-phellandrene

Nitrosates may be prepared by the action of nitrogen tetroxide or peroxide on an olefin. The product obtained is the dimeric bisnitrosate, and its formation may be represented by the equation:



$$\begin{array}{c} \diagdown\ \diagup \\ C \\ \| \\ C \\ \diagup\ \diagdown \end{array} + N_2O_4 \longrightarrow \begin{array}{l} -C-NO \\ \quad | \\ -C-O-NO_2 \end{array} \longrightarrow \text{dimeric form}$$

nitrosate

Nitrosates are said to be formed by other reactions. Semenov,[25] for example, obtained a compound of the composition $C_2H_4 \cdot N_2O_4$ from ethylene and nitrogen tetroxide. However, Dem'yanov reported a substance with different physical properties and the formula $C_2H_4 \cdot N_2O_3$.[26] Pentene combines with nitrogen tetroxide to give a nitrosate which decomposes on heating to 100°C.[27] A similar product is prepared from trimethylethylene[28] either by nitrogen tetroxide or by concentrated nitric acid and amyl nitrite in glacial acetic acid solution.

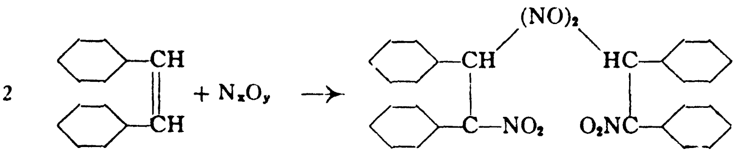
[24] See also R. Dulou, *Bull. inst. pin.*, 1934, 129; *Chem. Abs.*, 1934, **28**, 7255; *Brit. Chem. Abs.* **A**, 1934, 1106.

[25] Semenov, *Jahresber.*, 1864, 480.

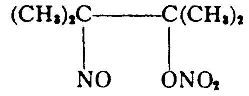
[26] N. Y. Dem'yanov, *Ann. Inst Agron. Moscow*, **4** (4), 155; *Chem. Zentr.*, 1899, **1**, 1064; *J.C.S.*, 1899, **76** (1), 845.

Passage of the nitrogen oxides generated by arsenious oxide and nitric acid into an ethereal solution of stilbene resulted in the formation of the pseudonitrosite[29] (bisnitrosonitro compound):



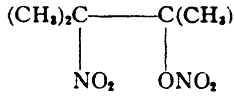
stilbene pseudonitrosite (m.p., 132°C.)

According to Dem'yanov[30] the interaction of tetramethylethylene and nitrogen tetroxide gives rise to a nitrosate and a nitro-nitrate:



$$\underset{\displaystyle NO}{(CH_3)_2\overset{}{C}}\text{———}\underset{\displaystyle ONO_2}{C(CH_3)_2}$$

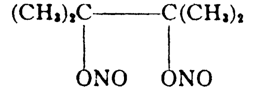
nitrosate



$$\underset{\displaystyle NO_2}{(CH_3)_2C}\text{———}\underset{\displaystyle ONO_2}{C(CH_3)_2}$$

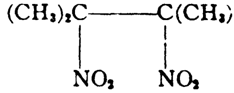
nitro-nitrate

On the other hand, Schmidt[31] reported that the products formed by this reaction were a dinitrite and a dinitrotetramethylethane:



$$\underset{\displaystyle ONO}{(CH_3)_2C}\text{———}\underset{\displaystyle ONO}{C(CH_3)_2}$$

tetramethylethylene glycol dinitrate

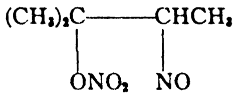


$$\underset{\displaystyle NO_2}{(CH_3)_2C}\text{———}\underset{\displaystyle NO_2}{C(CH_3)_2}$$

dinitrotetramethyl ethane

He reported the formation of diphenyl dinitroethane from stilbene.[32]

There is also some controversy as to the products obtained from the action of nitrogen pentoxide on unsaturates. Thus, Dem'yanov[33] observed the formation of $(C_4H_8N_2O_3)_2$ from butene-2, and of glycol dinitrate (b.p. 114-116°C.) from ethylene. The latter result has been found to occur when the ethylene has not been rigorously dried.[34] Dem'yanov found furthermore that, whereas trimethylethylene reacted with nitrogen pentoxide to give a nitrosite, tetramethylethylene formed a



$$\underset{\displaystyle ONO_2}{(CH_3)_2C}\text{———}\underset{\displaystyle NO}{CHCH_3}$$

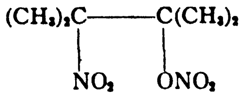
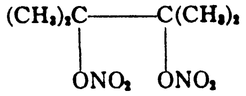
mixture of the nitro-nitrate and dinitrate:



$(CH_3)_2C(NO_2)-C(CH_3)_2(ONO_2)$

nitro-nitrate



$(CH_3)_2C(ONO_2)-C(CH_3)_2(ONO_2)$

dinitrate

The action of nitric acid, fuming nitric acid and nitrating acid (nitric and sulphuric acids) on ethylene gives different results. Kekule[35] stated that cold, mixed sulphuric-nitric acid produced ethylene glycol nitrate nitrite ($ONOCH_2CH_2$-ONO_2). On the other hand, Akestorides[36] held that ethylene was oxidized by fuming nitric acid to give oxalic acid and carbon monoxide. Haitinger[37] reported that the direct nitration of 2-methylpropene gave small amounts of the 2-methyl-1-nitropropene-1 and some butene dinitrite:[38] $(CH_3)_2C(ONO)-CH_2(ONO)$. There was, however, considerable oxidation leading to the formation of carbon dioxide, aliphatic acids and acetone.

Woodbury[39] has found that the direct nitration of an olefin with 2 to 4 carbon atoms by mixed nitric and sulphuric acid gives a highly explosive material. The nitrated substance is said to consist of a mixture of ethylene glycol dinitrate and 2-nitroethyl nitrate. A typical example of an explosive mixture is:

2-Nitroethyl nitrate	6 per cent
Ethylene glycol dinitrate	12 ” ”
Trinitroglycerol	22 ” ”
Sodium nitrate	46 ” ”
Wood meal	13 ” ”
Chalk	1 ” ”

The advantages of the incorporation of this nitrated ethylene are said to be lower cost (since cracking gases are employed as raw material) and lowering of the freezing point of dynamite prepared from it.[40]

The mechanism of the reaction of nitric acid and an olefin has been studied by Michael and Carlson[41] and by Wieland and co-workers.[42] The latter believed that combination took place by introduction of HO and NO_2 groups to form a nitrohydrine:

$-C(OH)-C(NO_2)-$

The hydroxyl group was then esterified to form α-nitroethyl-nitrate. On the other hand, according to Michael and Carlson, nitration of ethylenic compounds is not caused by nitric acid, but by oxides of nitrogen present in the reaction mixture. They state, moreover, that nitration by mixed nitric and sulphuric acids probably occurs by the addition:

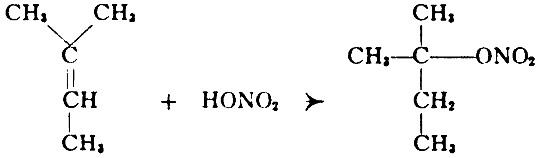
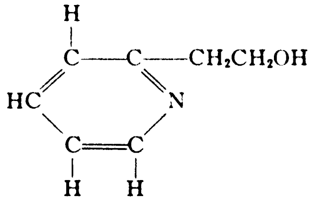
with the subsequent replacement of the $-SO_3H$ group by the more active nitro group. In contrast to the results of Wieland and Rahn,[43] Michael and Carlson show that at −20°C. the addition of trimethylethylene to an excess of "absolute nitric acid" in carbon tetrachloride gave largely the ester formed by the reaction.



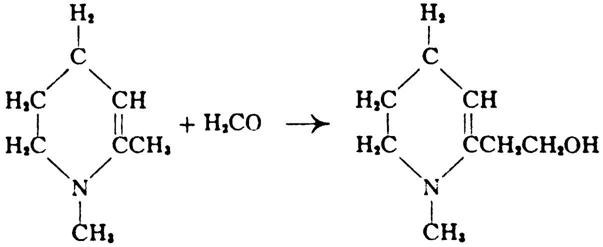
On standing at room temperature for 3 or 4 days, the *ter*-amyl nitrate produced in the above manner decomposed into high boiling substances. Dimethylaniline gave rise to isoamylene and the amine nitrate. Saponification of the latter by warm aqueous alkali produced isoamylene and 2-methylbutanol-2.

Reaction of Olefins with Aldehydes

These condensations were first investigated in 1889 by Ladenburg,[44] who reported the combination of 2-methylpyridine and formaldehyde which resulted in the formation of a compound which he called "α-picolyalkine," i.e., 2-(2′-pyridyl)-ethanol.



An analogous procedure using acetaldehyde gave the corresponding derivative of isopropanol. Subsequently, Lipp[45] found that an aqueous solution of methyltetrahydropicoline and formalin condensed to yield a base, according to the reaction:



Ladenburg,[46] however, stated that the product could be hydrogenated and dehydrated to give a bicyclic compound, and he assigned a somewhat different formula:

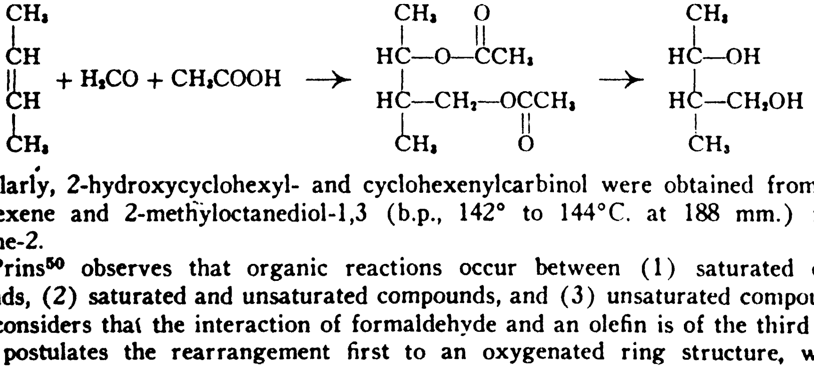
Union between formaldehyde and terpenes such as pinene, limonene and dipentene, may be effected by heating under pressure for about 12 hours at temperatures of 170° to 195°C.[47] Alcohol is employed as the solvent. The addition of formaldehyde apparently results in the formation of primary alcohols, as the reaction products readily give characteristic esters with either acetic anhydride or benzoyl chloride.

Aliphatic or hydroaromatic olefins are said to condense with formaldehyde to form glycols.[48] Thus, 45 liters of butene-2 may be absorbed in a solution containing 66 g. trioxymethylene in 440 g. glacial acetic acid and 62 g. concentrated sulphuric acid. The temperature must be maintained below 40°C. The solution is diluted with 500 cc. water and the diacetate of 1,2-dimethylpropanediol-1,3 separates as a liquid. Rectification gives 300 g. of product (b.p., 100-108°C. at 188 mm.) from which the glycol[49] (b.p., 112-118°C. at 25 mm.) may be prepared by saponification.



Similarly, 2-hydroxycyclohexyl- and cyclohexenylcarbinol were obtained from cyclohexene and 2-methyloctanediol-1,3 (b.p., 142° to 144°C. at 188 mm.) from octene-2.

Prins[50] observes that organic reactions occur between (1) saturated compounds, (2) saturated and unsaturated compounds, and (3) unsaturated compounds. He considers that the interaction of formaldehyde and an olefin is of the third type and postulates the rearrangement first to an oxygenated ring structure, which reacts further to give three possible products:

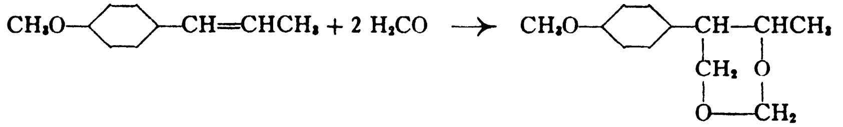
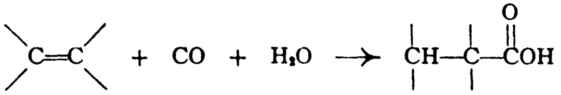
The presence of acetic acid may cause the formation of an acetate. Thus, 104 g. of styrene are added to a solution of 33 g. trioxymethylene and 32 g. concentrated sulphuric acid in 320 g. glacial acetic acid, the temperature being kept below 50°C. After several hours, the mixture is diluted with water and extracted. The oil recovered in this way is distilled and saponified. The product consists of 2-phenylpropanediol-1,3 and its methylene ether. However, from *p*-propenylmethoxybenzene (anethole) only the methylene ether was obtained.



There has been some projected commercial application of the reactions of aldehydes and olefins in forming resins and in refining petroleum fractions. Day[51] treated furfuraldehyde and a cracked gasoline with concentrated sulphuric acid. The mixture was refluxed and on cooling, a black gelatinous mass separated after about 20 minutes. By mixing the mass with wood flour, it can be worked into molded products. Thus from the olefins obtained in the sulphur dioxide extraction of cracked gasoline, acetone-soluble resins may be synthesized which are reported utilizable as substitutes for shellac. Levine[52] has proposed refining cracked distillates by vapor phase reaction with formaldehyde or acetaldehyde in the presence of hydrogen chloride and aluminum or zinc. On the other hand, Fulton[53] has recommended the removal of undesirable constituents in the presence of acetic acid and a condensing agent. Oil-soluble resinous substances may be separated by distillation. An oil may be treated, for example, with a mixture of equal parts by weight of concentrated sulphuric acid, glacial acetic acid and formaldehyde, and then distilled.

REACTIONS OF OLEFINS AND CARBON MONOXIDE

The commercial applications of carbon monoxide are so numerous that it is impossible to treat them except cursorily in this volume. The carbon monoxide-hydrogen synthesis of hydrocarbons will be discussed in Chapter 52. At this point a short discussion will be given of the synthesis of acids by the interaction of carbon monoxide, olefins and steam:



A large number of catalysts have been suggested to promote this reaction. Thus, Carpenter[54] has proposed several promoters such as non-volatile inorganic acids (e.g., phosphoric) either alone or with a volatile halide such as hydrogen chloride, or the halides of alkali or alkaline earth metals or of copper, iron, cobalt, nickel, bismuth, manganese, lead, titanium, zinc or cadmium alone, or with hydrogen halides, and further, the combined acidic oxides of groups 3 to 6 of the periodic system (such as silicomolybdic acid). The acid salts of phosphorus, arsenic, tungsten, molybdenum, uranium, chromium, vanadium, boron, silicon, or zirconium, (for instance, calcium monophosphate) were also suggested. Woodhouse[55] prefers to form the volatile inorganic acid (such as hydrochloric) *in situ* from chlorine in the presence of activated carbon. Among other catalysts recommended are: boron phosphate,[56] ammonium halides,[57] and alkali or alkaline earth fatty acid salts, alkoxides, carbonates or hydroxides.[58]

A process involving the liquid phase condensation of carbon monoxide and the unsaturated substances obtained in the cracking of petroleum oils has been advocated by Schalch.[59] In this method, the reactions are carried out with finely divided nickel, or various metallic oxides, suspended in the liquid.

Hardy[60] reported the interaction of ethylene, propene and butene-2 with carbon monoxide and steam in the presence of phosphoric acid with the formation of propionic, isobutyric and trimethylacetic (i.e., pivalic) acids. This confirmed his belief that the reaction of alcohols, carbon monoxide and steam proceeded by the intermediate elimination of water.[61]

CONDENSATION OF ALKENES WITH ALKYL HYPOCHLORITES

The addition of alkoxy chlorides (alkyl hypochlorites) to double bonds is not generally understood, and there is some difference of opinion as to the products formed. Both methyl and ethyl hypochlorite have been prepared by Sandmeyer through treatment of an alkaline solution of the alcohol with chlorine.[62] No reaction was observed when carbon dioxide, ethylene, amylene, acetylene or diethyl fumarate was allowed to act on ethyl hypochlorite. Subsequently, Goldschmidt, Endres and Dirsch[63] investigated the reaction of the latter substance. They reported that in most cases saturation of double bonds occurred as though hypochlorous acid were present. Thus amylene, cyclohexene and indene gave the corresponding chlorohydrins. Similar results were brought about by the reaction with acetylenes: phenylacetylene, for example, giving ω,ω-dichloroacetophenone. In other instances, ethyl hypochlorite acted as chlorinating agent, but it apparently added to 1,4-dihydronaphthalene with the formation of an inseparable mixture which included the product of the addition of an ethoxy and chloro group

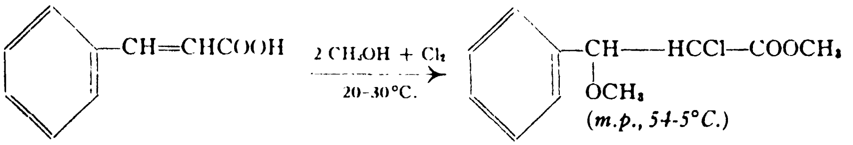
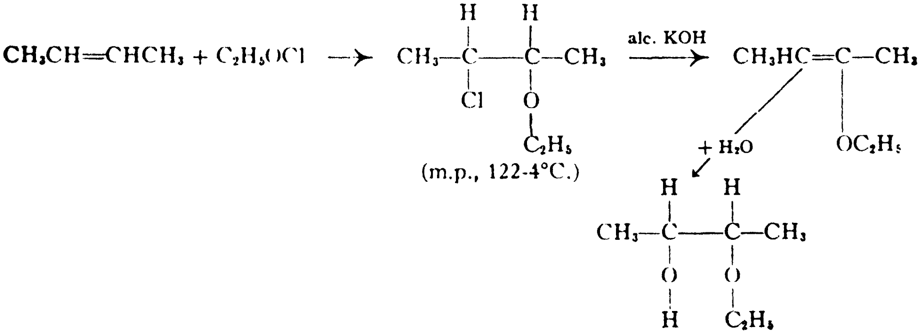
The union of hypochlorous esters with olefinic acids yields considerable quantities of the chlorohydrins or their lactones, but only small amounts of the chlorohydrin ethers. Thus, hex-3-enoic acid and ethyl hypochlorite in ether gave 93 per cent of isomeric 2-chlorohexolactone.[64] On the other hand, Jackson and Pasiut[65] have obtained small proportions of 1-chloro-2-alkoxy-2-phenylpropionic acids (substituted dihydrocinnamic acids) by the reaction of cinnamic acid in alcohol and chlorine. The alcohols used were ethyl and *ter*-butyl, the conversion being slightly better with the latter. With methanol, Jackson[66] reported 55 per cent of the methyl ester of 1-chloro-2-methoxy-2-phenyl propionic acid. Likewise, bromine could be substituted for chlorine.



Likhosherstov and Alekseev[67] have studied the action of alkyl hypochlorites on butene-2 (pseudo-butene) and reported the formation of ethers of 3-chlorobutanol-2. The reactant was prepared by the method of Sandmeyer,[68] and reacted with the olefin by dropwise addition to the latter at —15°C. The alcohols corresponding to the hypochlorite were used as solvents. The process, termed chloroalkoxylation, followed the equation:



$$CH_3CH{=}CHCH_3 + C_2H_5OCl \longrightarrow CH_3-\underset{Cl}{\overset{H}{C}}-\underset{\underset{C_2H_5}{O}}{\overset{H}{C}}-CH_3 \xrightarrow{\text{alc. KOH}} CH_3HC{=}\underset{OC_2H_5}{C}-CH_3$$

(m.p., 122-4°C.)

$$\xrightarrow{+H_2O} CH_3-\underset{\underset{H}{O}}{\overset{H}{C}}-\underset{\underset{C_2H_5}{O}}{\overset{H}{C}}-CH_3$$

The subsequent reactions of the chloro-ether to give an ether of enolic butanone-2, and hydration of the latter are also shown. The halogenated ethers are said to be colorless liquids with pleasant odor. They are distillable at atmospheric pressure, and are miscible with alcohol, ether and chloroform, but not with water.[69]

Langedijk[70] has also employed a mixture of *ter*-butyl hypochlorite and water in a gas-tight container as an absorbent for ethylene. From the reaction mixture, *ter*-butyl alcohol and ethylene glycol were recovered, the latter in 75 per cent yield.

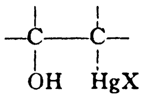
Ethylene glycol hypochlorite has been said to react with ethylene or other olefins to produce a dichlorodialkylether.[71]

COMPOUNDS OF OLEFINS WITH INORGANIC SALTS

Many olefins react with inorganic salts to form well-defined compounds of a complex nature which are usually represented by simple ratios of molecules of the compounds. Mercury salts, for example, appear to have an especial tendency toward this type of combination, and give a compound with the probable formula:



$$-\underset{OH}{\overset{|}{\underset{|}{C}}}-\underset{HgX}{\overset{|}{\underset{|}{C}}}-$$

This reaction is relatively specific for olefins, and has been used in their quantitative estimation.[72] The substances obtained by the action of mercuric acetate on cyclohexene, methylcyclohexene or octahydronaphthalene have also been suggested as disinfectants for grain.[73]

The earliest example of the formation of an olefin complex was reported by Zeise in 1831.[74] He obtained the compound $K(PtCl_3 \cdot C_2H_4) \cdot H_2O$ from the reduction of platinic chloride with alcohol. The analogous derivatives of propene and pentene have been investigated[75] as well as the corresponding potassium ethylenetribromoplatinite $K(PtBr_3 \cdot C_2H_4)$. The compounds of unsaturated acids, alcohols and aldehydes have been prepared by Biilmann and his co-workers[76] and by Pfeiffer and Hoyer.[77] The reactions of Zeise's salt, i.e., potassium ethylene trichloroplatinite monohydrate, have been investigated by Anderson.[78] Ethylene is liberated by the action of potassium cyanide or of pyridine on the salt, whereas with water at 90°C. or higher, the effect is partly the freeing of ethylene and partly the formation of acetaldehyde and platinum:

$$K(PtCl_3 \cdot C_2H_4) + H_2O \longrightarrow KCl + 2\ HCl + Pt + CH_3CHO$$

Although ethylene reacts readily, it was noted that styrene, indene, cyclohexene, 1,1-diphenylethylene and 1-phenyl-1-methylethylene were progressively more difficult to interact to give complexes. Kharasch and Ashford[79] have isolated coordination compounds of the type $(Un \cdot PtX_2)_2$ by combination of a platinic halide $(PtCl_3)$ with an unsaturated compound (indicated above by Un). These investigators point out that although the most direct method for the preparation of these substances would be by direct union of olefins and platinous chloride $(PtCl_2)$, yet because of the insolubility and inertness of the latter, attempts to apply this method are usually unsatisfactory. Their procedure consisted in suspending platininc chloride in glacial acetic acid; adding the olefin and warming on a steam bath to effect solution and reaction.

By passing ethylene into an ethereal solution containing a hydrogen chloride molybdic anhydride complex, glycol molybdate is said to result.[80]

$$MoO_2 \cdot 2HCl \cdot 2(C_2H_5)_2O + C_2H_4 \xrightarrow{(C_2H_5)_2O}$$

The organometallic product is a white hygroscopic powder, soluble in alcohols, but decomposed by water. It turns blue in the light. In this connection it is interesting to note that a somewhat similar reaction takes place if either cyclohexene or ethylene is treated with mercuric nitrate and iodine.[81] The product is thought to be an iodo alkyl nitrate:

$$2CH_2{=}CH_2 + Hg(NO_3)_2 + 2\ I_2 \xrightarrow[\text{solution}]{(C_2H_5)_2O} HgI_2 + 2\ CH_2ICH_2ONO_2$$

A reaction which is somewhat similar to those between olefins and various organic oxygen compounds occurs when aqueous solutions of alkali hydroxides and basic aluminum compounds are heated with olefins at 300° to 400°C. at superatmospheric pressures.[82] In this manner, propene may be oxidized to give potassium acetate in a 30 per cent yield.

$$C_3H_6 + KOH + H_2O \longrightarrow KOOCCH_3 + CH_4 + H_2$$

Similarly by heating 250 g. of water and 90 g. potassium hydroxide under 25.5 atmospheres pressure of ethylene in a 2 liter autoclave, Hofsäsz has been able to obtain 71.5 g. of acetic acid.[83]

By condensation of olefinic substances with unsaturated carbonyl compounds, such as maleic anhydride, it is said to be possible to prepare substituted polycarboxylic acids.[84] Dreyfus[85] has suggested that olefins such as ethylene may be condensed with cellulose and other carbohydrates by heating at 100° to 200°C. in the presence of a catalyst and under pressure.

OTHER REACTIONS OF OLEFINS

The action of thiocyanogen on olefins is similar in many respects to that of the halogens. This principle has been employed in the analysis of fats and oils analogous to the iodine method.[86] The solution of thiocyanogen may be prepared by suspending pure, dry lead thiocyanate in anhydrous acetic acid and adding bromine, according to Krassilchik.[87] Solutions below 0.1*N* are said to be stable. A disadvantage of this reagent, which has been used in the study of many oils and fats[88] is the time necessary for equilibrium. Caldwell and Piontkowski[89] have found that 1 to 2 hours sufficed for reaction of an oil with the Hanus iodine bromide solution, whereas 47 hours were required with the Kaufmann thiocyanogen reagent. There is also some interference from alcoholic substances and from steric hindrance of the double bond.

According to Lippmann, benzoyl peroxide and amylene (a mixture of isomeric hydrocarbons boiling at 35° to 40°C.) combine quite violently at 100°C. and 10 atmospheres pressure.[90] The reaction mixture was separated into benzoic acid, small quantities of benzoic anhydride, pentane, carbon dioxide and a light oil, of a pleasant ethereal odor. The latter was evidently a mixture of benzoates, as on saponification it yielded potassium benzoate and a clear yellow oil, of which about one-half consisted of an amyl ether ($C_{10}H_{20}O$, b.p., 198-203°C.).

Chapter 26

Polymerization of Monolefins and Diolefins. Synthetic Polymerization Products

Numerous researches on the polymerization of olefins have been stimulated by the huge volumes of gaseous unsaturated hydrocarbons obtained in the cracking industry. Formerly these substances were considered of little value and allowed to escape into the atmosphere, but later developments have led to their recovery and subsequent utilization, particularly conversion to alcohols[1] (both mono- and dihydric) or to hydrocarbons of higher molecular weights by polymerization. The latter is exemplified by the production of synthetic gasoline or lubricating oils and synthetic rubber. Egloff has shown that in 1935 alone there was available a potential supply of 9,000,000,000 gallons of polymer gasoline, which could have been recovered from cracking gas as the source of raw materials.[2]

Strictly speaking, polymerization from this standpoint involves the combination of unsaturated molecules to form larger molecules. Paraffins do not yield polymers directly but they may be dehydrogenated or cracked to olefins.[3] Polymerization reactions are exothermic and occur at low temperatures, while pyrolysis reactions are endothermic and require high temperatures, so that in general a two-stage treatment is required when paraffin hydrocarbons are used. As a result of their experiments, Sullivan, Ruthruff and Kuentzel[4] have concluded that one-step processes are inferior to the two-step for these hydrocarbons. However, Keith and Ward,[5] in their work on the Unitary (one-stage) process, do not agree with this observation and state that the one-step process may be used advantageously with paraffins, under the proper conditions. These investigators also present evidence to show that direct reaction of saturated and unsaturated molecules may and does occur under these circumstances.[6]

From free energy calculations it can be shown that olefins are unstable below about 425°C. Below this temperature these hydrocarbons tend to polymerize, and isomerization of the higher members of the series to the corresponding naphthenes is also possible.[7] Cracking of olefin hydrocarbons to lower molecular weight hydrocarbons generally takes place above 425°C. The products usually obtained may be classified as (1) olefin polymers and naphthenes, (2) higher olefins, paraffins, naphthenes and polynaphthenes and (3) aromatics (resulting from secondary reactions). These three types result by treatment at progressively higher temperatures.

MECHANICS OF POLYMERIZATION

Polymerization is a composite process, and the development of a complex molecule must require a series of consecutive reactions.[8] The latter may be regarded from two viewpoints, that is, either as a series of step-wise reactions or a chain mechanism.[9] In the first of these hypotheses, a substance is thought to polymerize primarily to the dimer, which then reacts with another molecule to form the trimer, which in turn unites with another monomer to give the tetramer, and so on. On the fundamental assumption that the rates of the consecutive polymerization reactions are not greater than that of the dimerization, Chalmers shows that the dimer and other low polymers (such as trimer and tetramer) would be formed in the largest amounts. However, this is not the case, as higher polymers normally predominate in the product. Furthermore, the reaction course of the monomer does not follow this proposed step-wise system. Chalmers, therefore, rejects this view and in its stead adopts a chain mechanism. The reaction chain is conceived as a primary activation of the monomer and a subsequent process of concatenation[10] which is rendered possible by the presence of free terminal bonds in all of the intermediate stages. The linking of the monomeric bonds initially proceeds at a rate which is almost instantaneous compared with that of the activation, but for very great chain lengths the speed becomes increasingly slow.

Gee and Rideal[11] consider polymerization to be a chain reaction in which the chains are broken by the operation of a steric factor (due to the arrangement of the molecules in space). According to this view the growth of chains may be terminated in several ways, as for instance (1) spontaneous deactivation, (2) by collision with a molecule of a monomer and (3) by partial deactivation. The importance of steric hindrance has been shown by Gee[12] who found that the proportion of the olefin polymerized before the maximum reaction velocity is attained varies from zero, with a strong deactivation, to 0.33 with no deactivation and zero steric factor, and finally approaches a value of 0.5 for large steric factors.

Dostal and Mark[13] look upon the mechanism as proceeding in two definite steps, the first of which is the formation of nuclei by collision of two monomeric molecules. This reaction requires an energy of activation and may be either uni- or bi-molecular. The second stage, rapid compared with the first, involves the growth of chains which may occur and be modified in a variety of ways. Applying this theory to the polymerization of styrene gave results in agreement with experimental observations.

[13] H. Dostal and H. Mark. *Z. physik. Chem.*, 1935, **29B**, 299; *Trans. Faraday Soc.*, 1936, **32**, 54; *Chem. Abs.*, 1935, **29**, 7162; *Brit. Chem. Abs.* **A**, 1936, 295.

A mechanism based upon the theories of free radicals and electronegativities has been proposed by Kline and Drake.[14] The two free radicals formed by the scission of a molecule are designated as positive and negative. Thus, (1) trimethylethylene behaves as if it were activated as:

$$(1)\quad (CH_3)_2C{=}CHCH_3 \longrightarrow \overset{-}{C}H_3 + CH_3\overset{+}{C}{=}CHCH_3$$

These two fragments then add to the double bond[15] of a non-activated molecule to form 3,4,5,5-tetramethylhexene-2,

$$(2)\quad \overset{-}{C}H_3{-}CH_3\overset{+}{C}{=}CHCH_3 + (CH_3)_2\overset{+}{C}{=}\overset{-}{C}HCH_3 \longrightarrow CH_3C(CH_3)_2CHCH_3CCH_3{=}CHCH$$

or may combine with the isomer to form 3,5,5-trimethylheptene-2,

$$(3)\quad \overset{-}{C}H_3{-}CH_3\overset{+}{C}{=}CHCH_3 + CH_3CH_2\overset{+}{C}CH_3{=}\overset{-}{C}H_2 \longrightarrow CH_3CH_2C(CH_3)_2CH_2CCH_3{=}CHCH_3$$

Both of these substances have been isolated in the condensation products of trimethylethylene. The same mechanism has also been applied to isobutene polymerization. From a consideration of the relative strengths of the carbon-hydrogen and carbon-carbon bonds, it may be expected that isobutene would have more of a tendency to split into negatively charged methyl and positively charged isopropenyl radicals than into positive hydrogen atoms and negative isobutenyl radicals. The products obtained in the polymerization can be accounted for on the basis that about 80 per cent of the molecules were activated in the first manner (giving rise to 2,4,4-trimethylpentene-1) and 20 per cent following the second (resulting in 2,4,4-trimethylpentene-2).

Catalysts. An application of thermodynamics to a reaction will indicate whether or not that reaction is thermodynamically possible at a certain temperature and pressure, and what the maximum yield will be at equilibrium. However, due to the fact that time is not a thermodynamic variable, this science furnishes no means of foretelling how long a duration will be required for equilibrium to be established.[16] In most polymerization reactions the velocity is extremely slow, so that equilibrium may be brought about only after several days. Since catalysts accelerate the speed of reaction and often bring about the transformations in an extremely short interval, the application of these agents to this field has become widespread.[17]

It should be borne in mind, however, that catalysts cannot increase the maximum thermodynamic yield; they merely speed up the rate of reaction to reach that condition in a shorter time. Catalysts may be selective, that is, exhibit definite preference for the acceleration of one reaction while not affecting, or perhaps even inhibiting, others in the same system.

There are two possibilities as to the mechanism of catalysis, according to Gee and Rideal.[18] The catalyst may initiate a chain center or it may form a reactive complex. The second view is considered the more probable one by these investigators, as it explains most experimental observations with reasonable exactitude. On the other hand the first is true only in a relatively small number of instances. In catalytic treatment the assumption that the velocity of a polymerization reaction and the size of the polymers produced diminish in the same ratio is shown to be not strictly accurate. Nevertheless, this is a good approximation in the early stages of reaction.

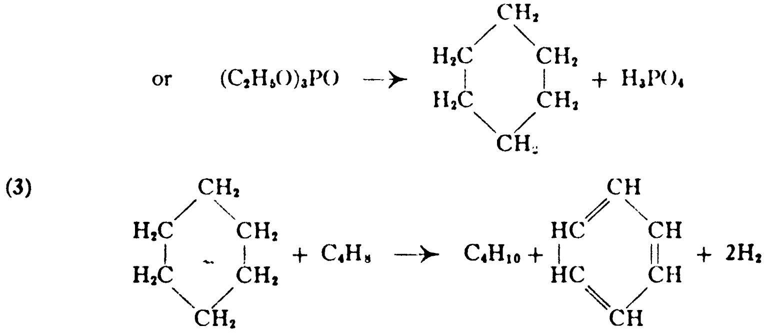
[17] The usefulness of catalysts in polymerization reactions has been discussed by A. E. Dunstan and D. A. Howes, *J. Inst. Pet. Tech.*, 1936, 22, 347; *Chem. Abs.*, 1936, 30, 6541; *J. Inst. Pet. Tech.*, 1936, 22, 352A; *Brit. Chem. Abs.* B, 1936, 915.

Phosphoric acid is one of the most common accelerators used for catalytic polymerizations. Ipatieff and Pines[19] explain the action of aqueous phosphoric acid as follows: (1) the formation of phosphate esters, (2) the decomposition of these esters to yield polymerides and naphthenes, (3) the dehydrogenation of naphthenes to aromatics and (4) the hydrogenation of olefins to paraffins by nascent hydrogen from the naphthenes. Using ethylene as the hydrocarbon, these reactions may be illustrated as:

$$\begin{array}{lrcl} (1) & C_2H_4 + H_3PO_4 & \longrightarrow & (C_2H_5O)H_2PO_3 \\ \text{or} & 2C_2H_4 + H_3PO_4 & \longrightarrow & (C_2H_5O)_2HPO_2 \\ \text{or} & 3C_2H_4 + H_3PO_4 & \longrightarrow & (C_2H_5O)_3PO \end{array}$$

$$(2) \qquad (C_2H_5O)_2HPO_2 \longrightarrow C_4H_8 + H_3PO_4$$



At temperatures below 200°C. the various phosphoric and phosphorous acids,[20] oxyhalides and acid esters of phosphorus[21] have all been recommended. It is often advantageous to use the phosphoric acid catalyst in a "solid" form in which siliceous adsorbents (e.g., kieselguhr or fuller's earth) are impregnated with the acid[22] or mixed with cadmium acid phosphate.[23] In aqueous solution, phosphoric acid may also be employed in conjunction with other acids, such as boric acid,[24] or with metallic salts,[25] especially of silver and copper.[26] Sulphuric acid may be substituted[27] but at lower operating temperatures,[28] especially when tertiary olefins are involved.[29] The latter acid has been suggested[30] for the conversion to liquid fuels of mixtures of olefins obtained by the dehydration of alcohols produced by the catalytic reduction of carbon monoxide under pressure (the so-called "Synthol" reaction).[31]

In addition to the acids mentioned, various metallic halides have been reported as being effective for the polymerization. Egloff has stated that pure, anhydrous aluminum chloride appears to be inactive, and that it is only in the presence of minute traces of moisture (and therefore hydrochloric acid) that this substance acts catalytically.[32] High-molecular-weight polymers may be obtained with boron trifluoride charged with hydrofluoric acid, phosphorus tri- or pentafluoride at

temperatures below —10°C. in the presence of an inert solvent[33] or with disubstituted boron fluorides (dihydrated, dialcoholated or diacetylated).[34] The use of nickel, iron and titanium chlorides[35] and fused zinc chloride at high temperatures[36] has also been suggested.

Clay mixed with diatomaceous earth,[37] nickel oxide,[38] or activated carbon[39] is sometimes used. Carbon monoxide[40] in the presence of nickel mixed with aluminum oxide has been reported as being very active. Oxygen also exerts a catalytic effect,[41] most likely due to the formation of an intermediate oxide which decomposes giving a bivalent radical of one or more carbon atoms.

ETHYLENE

Storch[42] investigated the kinetics of the polymerization of ethylene at 377°C. and 1415 mm. pressure with heating times of 1 to 3 hours. Butene is the primary product and propene evidently a secondary one. Minute traces (0.02 per cent) of oxygen doubled the reaction rate, and because of the difficulty of entirely removing this element from ethylene, reproducible rates of polymerization could not be obtained. The addition of ethyl mercaptan (0.1 per cent concentration) decreased the rate about tenfold. However, in the latter case the speeds were duplicable within about 5 per cent.[43] Evidence obtained shows that the reaction is not a simple bimolecular process. The energy of activation is given as 43,500 cal. Investigations by Krauze, Nemtzov and Soskina[44] showed that at 315-380°C. with high ethylene concentrations, the reaction is practically homogeneous and of a bimolecular nature. No catalytic action was imparted by iron, nickel, copper, chromium, zinc oxide or activated carbon. Rapid polymerization is said to result at 300°C., however, if azomethane is introduced in small amounts.[45]

By contacting ethylene with boron trifluoride and a promoter such as nickel embedded on a carrier, good yields of butene may be obtained at 8 to 10°C. and 50 atmospheres pressure at relatively short contact times. Longer periods of contact yielded almost exclusively liquid products.[46]

Polymerization of ethylene in the presence of phosphoric acid at 250-300°C. and 50 to 65 atmospheres pressure, according to Ipatieff and Pines, furnishes a mixture of paraffinic, olefinic, naphthenic and aromatic hydrocarbons. On the other hand, thermal treatment of the olefin under the same conditions gives no aromatics and only small percentages of paraffins.[47] There is no evidence of cracking in the catalytic treatment. Table 130 lists the boiling ranges of the liquid products formed by the catalytic operation. From measurements of the indices of refraction and densities, the concentration of paraffins was believed to be greatest in the lowest boiling fractions, while aromatics predominated in those boiling above 225°C. Naphthenes were present in the fractions above 110°C. An interesting observation was that isobutane was formed to the extent of 2.5 per cent at 250°C. and 18.8 per cent at 330°C. (based on the weight of ethylene reacting). The presence of isobutane is attributed to isomerization of the 1- or 2-butene (formed during polymerization) to isobutene and subsequent hydrogenation of the latter. At slightly higher temperatures (300-360°C. and 60 atmospheres pressure) with a "solid" phosphoric acid catalyst (H_3PO_4 embedded on kieselguhr) the reaction is said to be 80 to 85 per cent complete, with about 90 per cent of the product being liquid.[48] The phosphoric acid catalyst was found to be equally effective when the contact material was used in the solid form or suspended in a liquid medium (the synthetic oil, Kogasin II[49] was the dispersing agent).

250	37	26	27	10
280	31	33	23	13
300	42	20	26	12
333	46	14	29	11

Malishev[50] has investigated the polymerization of ethylene using a catalyst composed of equal parts of phosphoric anhydride and lampblack. Under 65 atmospheres pressure, the rate of the reaction was quite slow at room temperature, but at 110°C., a rapid fall of pressure occurred. The reaction was completed at 260°C. after a 2-hour period of heating. About 40 per cent of the ethylene was converted into a liquid boiling between 20° and 240°C. containing olefins, paraffins, aromatics and naphthenes. Malishev believed that phosphoric anhydride is a more active catalyst for polymerizations than is phosphoric acid, and is somewhat similar to aluminum chloride in its action.

Egloff and Schaad have shown that polymerization of ethylene takes place more readily in a static than in a dynamic system.[51] Employing an autoclave at 50 atmospheres pressure, a 63 to 73 per cent conversion to liquids was obtained at 380°C. With a steel tube, however, a temperature of 420°C. was required for the same yield at 50 atmospheres pressure. Butadiene and paraffins up to nonane were found in the product. Aluminum oxide exerted very little catalytic action, but when a mixture of the oxides of nickel, aluminum and copper was employed as a catalyst at 330°C., an explosion resulted giving carbon, hydrogen and methane.

Conversion of ethylene to liquid fuels by thermal treatment has been investigated by Sullivan, Ruthruff and Kuentzel.[52] In their experiments, carried out in high pressure bombs at temperatures of 370 to 455°C., the interdependence of the three variables, temperature, pressure and time of contact, was very clearly shown. In this series of tests, during the initial heating period the ethylene was introduced into the bomb at a low rate of flow. When the operating temperature was reached, the flow was increased to a predetermined value, after which all conditions were maintained as constant as possible. At very high pressures, conversion to liquids increased very rapidly with increasing time of contact up to a maximum, after which cracking of the polymer occurred. In Table 131 are summarized the conditions for maximum polymer yield and the effect of pressure on the reaction.

TABLE 131.—*Effect of Pressure on the Thermal Polymerization of Ethylene.*

Pressure lbs./sq. in.	Temperature °F.	Time of Contact Min.	Liquid Yield %	Gravity of Liquid °API	Gasoline Boiling Below 390°F. %	Octane No. of Gasoline
500	850	8.1	59.1	49.0	73.8	78
1000	850	27.4	70.0	49.3	69.5	68
2000	850	22.4	80.8	48.0	62.5	64
3000	700	85.0	75.0	46.5	40.2	62
3000	750	43.0	74.8	47.5	47.3	63
3000	800	17.3	74.3	47.7	55.0	62
3000	850	9.6	71.4	50.1	67.1	63

An investigation covering pressures of 34 to 90 atmospheres at temperatures of about 400°C. was conducted by Smolenski and Kowalewski.[53] In their procedure, ethylene under pressure was very slowly heated up to the operating temperature (requiring about 5 hours). This precaution is quite important, because under these pressures if the ethylene is heated too rapidly an explosion will occur (resulting in the formation of methane and carbon). The polymerization was then carried out by maintaining the gas at 400°C. for 2 to 2.5 hours. This treatment resulted in an almost complete conversion to liquid products which ranged from hydrocarbons of the gasoline fraction to those of lubricating oils, depending upon the pressure employed. The yields of the various fractions are listed in Table 132. The portions boiling up to 250°C. were refined by treatment with sulphuric acid and subsequently washed with water and sodium hydroxide, removing 20 to 25 per cent of unsaturated and aromatic hydrocarbons. The refined liquids contained mainly paraffins with slight amounts of naphthenes. Hydrogenation of the crude product under 90-100 atmospheres pressure diminished the yield from 92 to 75-80 per cent of liquid product, which contained 15 to 20 per cent of unsaturates.

TABLE 132.—*Liquid Products from Non-Catalytic Polymerization of Ethylene at 400°C.*

Pressure, atmospheres	34	51	90
Yield of crude liquid, %	80	92	97
Density, 20°C.	0.764	0.775	0.792

Fractions from Distillation of Crudes
(Per Cent of Total Volume)

Below 150°C.	45.6	29.5	19.5
150-250°C.	39.6	42.5	28.5
275-300°C.	6.0	6.6	6.8
Over 300°C.	8.2	21.0	43.5

The reduction in yield is attributed to rupture of long chains and the subsequent hydrogenation of the fragments. Further experimentation showed that at 420°C. and pressures of 67-210 atmospheres depolymerization takes place, with the cyclization of olefins to give naphthenes and dehydrogenation of these substances to produce aromatics. Smolenski and Kowalewski point out that the chemical character of polymerization products depends more on the temperature than on the presence of a catalyst of the type of alumina. Liquid products may also be produced by passing ethylene over metal surfaces either coated or alloyed with tin, zinc, aluminum or chromium at 400 to 900°C.[54]

---

[53] K. Smolenski and S. Kowalewski, *Bull. intern. acad. polonaise. Classe sci. math. nat.*, **1934A**, 315; *Chem. Abs.*, 1935, **29**, 1058; *Brit. Chem. Abs.* **A**, 1935, 191; *Przemysl. Chem.*, 1934, **18** (10-12), 547; *J. Inst. Pet. Tech.*, 1935, **21**, 132A; K. Smolenski, *Brennstoff-Chem.*, 1934, **15**, 212.

By heating lower olefins to 400-700°C. for short contact times (less than 2 seconds) in the presence of 0.5 to 1 per cent of oxygen in a reactor having a large volume-surface ratio, higher olefins are very readily produced. At 600°C. under these conditions, ethylene gives 59.3 per cent propene, 12.2 per cent butene and 28.4 per cent pentene.[55] No dissociation to carbon and hydrogen or excessive formation of methane or other paraffins is said to result at this temperature. Above 650°C., however, the polymers undergo cracking, which reduces the yield. The maximum degree of polymerization is reported to occur in the range of 550° to 650°C. using unpacked glass or metal tubes. The formation of carbon may be retarded by the addition of about 0.1 per cent of sulphur dioxide to the gas, which is then passed over a copper catalyst at 450-750°C.[56] The introduction of nascent hydrogen into the mixture of ethylene and sulphur dioxide prior to catalytic treatment has also been proposed to avoid the production of unsaturated liquid hydrocarbons.[57]

PROPENE

The kinetics of the polymerization of propene at 330 to 400°C. have been investigated by Krauze, Nemtzov and Soskina.[58] The reaction progressed in a manner analogous to that of ethylene, and is apparently of the second order kinetically. The activation energy is calculated to be 37,400 cal., and the variation of the equilibrium constant with the temperature is given by:

$$\log_{10} k = 10.23 - \frac{8320}{T}$$

Liquid orthophosphoric acid is a very effective catalyst for the polymerization of propene at temperatures as low as 130°C. At moderate conditions (135 to 200°C. and 1 to 15 atmospheres pressure), this hydrocarbon is said to be capable of transformation into a liquid consisting almost entirely of iso-structure monolefins, such as hexenes, nonenes, dodecenes and pentadecenes. At higher temperatures and pressures and with longer contact times, naphthenes, aromatics and paraffins also result.[59] At 330 to 370°C. and high pressure, the degree of unsaturation of the products is much greater in the catalytic than in the thermal treatment. The types of hydrocarbons formed are the same, except that in the latter case, cycloparaffins and cycloölefins predominate, while aromatics are absent. Table 133 gives the approximate percentage composition of the products obtained by the thermal and catalytic polymerization of propene.[60]

According to Sullivan, Ruthruff and Kuentzel[61] propene does not yield as large a conversion to liquid fuels as ethylene under the same conditions of thermal polymerization. However, the specific gravity of the liquid, percentage boiling in the gasoline range and the octane number of this gasoline fraction are all much higher than with the ethylene polymer. The optimum results are given in Table 134, which also shows the effect of high pressure treatment.

TABLE 134.—*Effect of Pressure on the Thermal Polymerization of Propene.*

Pressure lbs./sq. in.	Temperature °F	Time of Contact Min.	Liquid Yield %	Gravity of Liquid °API	Gasoline Range Boiling Below 390°F. %	Octane No. of Gasoline
500	850	5.7	16.3	53.2	80.3	78
1000	800	22.6	46.9	53.6	73.1	87

3000	850	8.7	61.2	50.3	67.1	74

Brandes, Gruse and Lowy[62] have studied low temperature polymerization of propene using zinc chloride carried on pumice stone. The effect of this catalyst can be seen from Table 135.

TABLE 135.—*Polymerization of Propene.*

Temperature, °C.	Pressure lb./sq. in.	Time of Contact Min.	Yield of Liquid %	Sp. Gr. Liquid
With Zinc Chloride Catalyst				
290-300	1600	90	74.2	0.7571
200-208	2050	60	43.5	0.7491
150-160	3400	360	64.4	0.7441
Without Catalyst				
290-308	2475	92	4.3	0.7665
200-215	2150	60	0.3	—
150-160	3350	360	0.2	—

Without the presence of the zinc chloride, practically no liquids were obtained, other conditions being approximately the same. Examination of the polymers showed that the chief constituents were olefins and paraffins, together with some naphthenes in the higher fractions. Complete absence of aromatic hydrocarbons was noted, however. The hydrocarbons produced are listed according to their carbon content in Table 136.

TABLE 136.—*Liquid Products Obtained from the Pressure Treatment of Propene Using a Zinc Chloride Catalyst.*

Operating Temp. °C.	Chief Constituents Present, Per Cent by Volume C_5	C_6	C_7	C_8	C_9	C_{10-12}	Per Cent Distilling in Gasoline Range (to 200°C.)
290-310	5.8	10.1	5.9	12.9	18.7	27.3	74.5
200-210	0.07	7.0	1.6	2.0	47.0	32.0	85.9
150-160	0.3	10.6	1.2	1.7	55.9	24.1	92.0

Oxygen in a concentration of 0.5 to 1.0 per cent favors the production of higher olefins from propene. The optimum conditions are given as 550° to 650°C., pressures up to 15 atmospheres and reaction times less than 2 seconds. At temperatures above 650°C., decomposition to carbon, hydrogen and paraffins is also noted, as in the case of ethylene. At 600°C. in the presence of 0.5 per cent oxygen, using a reactor having a large volume-surface relation, the following unsaturated hydrocarbons are formed: 9.3 per cent butene, 27.4 per cent pentene, 32.3 per cent hexene, and 30.4 per cent higher olefins b.p. 74-100°C.[63]

BUTENES

Polymerization reactions of 2-butene and isobutene are homogeneous and of the second order, according to Krauze, Nemtzov and Soskina. The velocity constants at 370°C. are governed by the equations

$$\log_{10} k = 10.0 - \frac{38,000}{2.3RT}$$

$$\text{and} \qquad \log_{10} k = 12.3 - \frac{43,000}{2.3RT}$$

respectively (R is the gas constant and T is the absolute temperature). As a general rule, the velocity constant decreases rapidly with increase in molecular weight in the case of the normal olefins, while the existence of two chains attached to the double bond increases the rate, as in isobutene.[64]

The calculations of Parks and Todd on the free energy change for the formation of diisobutylene from isobutene following the reaction

$$2C_4H_8 \text{ (gas)} \rightleftharpoons C_8H_{16} \text{ (liquid)}$$

give $\Delta F°$ of −6,930 cal. at 298°K. (25°C.). This negative value for the free energy change means that the reaction may be expected to proceed spontaneously from left to right, since the equilibrium constant is related to the change in free energy by the equation:

$$\Delta F° = -2.3RT \log K$$

It is of interest to note the approximate temperature limitations deduced by thermodynamics for this reaction. On the assumption that the free energy change may be expressed as a linear function of the absolute temperature (which is equivalent to taking the difference in the specific heats of the products and the reactants equal to zero), it can be shown that the above reaction is not possible at ordinary pressure above 402°K. (129°C.).[65]

Ipatieff and Corson found that the rate of polymerization of the butenes using aqueous phosphoric acid as catalyst increased in the order 1-butene, 2-butene and isobutene. The liquid polymerization products are similar in physical and chemical properties, all being mixtures of liquid monolefins. Mild conditions (30°C.) favor the formation of only two simple polymers (dimer and trimer). At higher temperatures, as many as seven compounds were obtained from isobutene, however diisobutene and triisobutene were the predominant resultants.[66]

In addition to polymerization, phosphoric acid causes considerable isomerization with the butenes.[67] For this reason Ipatieff and Corson point out the fact that there may be doubt as to the reliability of the relative rates of polymerization that they reported. For instance, although the starting hydrocarbons were pure specimens, the material which was actually polymerized might have been a mixture of the isomeric butenes, the relative amounts of which would depend upon the experimental conditions. In the light of this, isobutene was observed to accelerate the polymerization of the *n*-butenes, while the latter affected the rate of polymerization of propene in the same manner. Sulphuric acid is particularly effective in selectively polymerizing isobutene to di- or to di- and triisobutylene from mixtures of olefins.[68]

Hydrocarbons of high molecular weight are produced from isobutene by the action of volatile metallic halides. Temperatures from —10° to about 50°C. are reported as effective when using beryllium chloride, zinc chloride, phosphorus pentafluoride, arsenic trifluoride, osmium octafluoride, boron trichloride, stannic chloride, titanium tetrachloride and antimony pentafluoride.[69] By means of boron trifluoride, isobutene may be polymerized at —15°C. to compounds having a molecular weight of 10,000-15,000. With a specially purified isobutene, treated with this promoter at —80°C., the molecular weight of the product may be increased to as high as 40,000.[70] In this connection it is interesting to note that treatment with aluminum chloride[71] at temperatures of —78° to 16°C. gives rise to olefins and cyclic products of molecular weights in the range of only 132 to 4800.[72]

Various silicates, such as silica gel and fuller's earth, render maximum catalytic effect after being activated at a temperature between 300° and 325°C.[73] According to Lebedev and Borgman[74] the factors of contact time, temperature and method of activation of the catalyst determine the yields and degree of complexity of the products. Activated floridin in contact with 2-butene at room temperatures for 1, 2 and 4 months produced 45-50, 60 and 80-85 per cent polymerization, respectively.[75'] The product consisted of 43 per cent of the dimer, 15-18 per cent of the trimer and the remainder higher polymers.

Lebedev and Borgman show that the molecular weight of the polymers increases uninterruptedly with falling temperature. At —65°C. floridin (activated at 200°C.) gives rise to compounds varying from 112 to 12,000 in molecular weight. The polymers of isobutene produced at —70°C. consisted of 3.4 per cent octene, 20.7 per cent dodecene ($C_{12}H_{24}$), 15.3 per cent hexadecene ($C_{16}H_{32}$), 10.8 per cent tetracosene ($C_{24}H_{48}$), 5.4 per cent octacosene ($C_{28}H_{56}$), and 44.4 per cent higher hydrocarbons.[76] The action of alumina precipitated on silica gel yields similar monolefins from isobutene, substances up to the tetramer being detected.[77]

HIGHER OLEFINS

Pentenes. The normal pentenes have been shown by Waterman and coworkers to cyclicize very readily in the presence of aluminum chloride.[78] Experiments with 2-pentene using this catalyst at low temperatures (0° to —80°C.) yielded partly cyclic compounds, some having a molecular weight of 350 and containing only a mono ring formation.[79] At 400°C. with or without aluminum oxide, the cyclic character of the polymerization products is augmented.[80] Isopentenes, such as methylethylethylene, trimethylethylene and isopropylethylene, using aluminum chloride at 85°C. and 200°C. and alumina at 400°C. yielded partly cyclic substances. Dimers formed about 20 to 25 per cent of the product.[81]

Hexenes. The thermal polymerization of 2-hexene and 3-methyl-2-pentene has been investigated by Nemtzov and Poletaev,[82] who report that both reactions are of the second order kinetically. The rate of polymerization of the normal hexene is about twice that of the branched isomer, and is considerably lower than that of ethylene and propene condensations. The chief component of the reaction mixture in each instance is the dimer, with little trimer and no higher polymers. According to these investigators, 2-hexene is more stable than isohexene, but olefins are much more easily decomposed by thermal treatment than the corresponding paraffins. The normal hexenes begin to polymerize above 350°C. in the presence of molybdenum sulphide. At 400°C. this reaction becomes quite marked, yielding principally higher boiling hydrocarbons. Considerable isomerization to 2-hexene was noted. Only small amounts of 3-hexene and no isohexene could be detected.[83]

Laughlin, Nash and Whitmore have studied the equilibrium mixture of three of the isomeric hexenes. Tetramethylethylene, methylisopropylethylene and *ter*-butylethylene, heated to 300°C., were each passed over a catalyst of silica gel impregnated with phosphorus pentoxide. The product obtained from these treat-

FIG. 142.—Experimental Catalytic Polymerization Plant. (A. E. Dunstan and D. A. Howes)

ments was a mixture of three isomers, and in each instance had the composition 61 per cent tetramethylethylene, 31 per cent *unsym*-methylisopropylethylene and 3 per cent *ter*-butylethylene. It is interesting to note that a mixture having the identical percentage composition results from the dehydration of methyl-*ter*-butyl carbinol (pinacolyl alcohol) with the same catalyst at 300°C.[84]

Cyclohexene. Cyclohexene may be converted into cyclohexyl-cyclohexene to the extent of 80 to 90 per cent by boiling with phosphorus pentoxide in a Soxhlet extractor.[85] Orthophosphoric acid also may be used, but is not as effective as the anhydride, and metaphosphoric acid (HPO_3) is without action.[86] Using aluminum chloride as a catalyst and liquid pentane as a diluent, Waterman, Leendertse and ter Poorten[87] observed that hardly any polymerization of cyclohexene took place at −78°C., and even at 40°C. the reaction was only slight, whereas with isobutene and isopropylethylene, reaction was quite violent at these temperatures. At 70°C., however, cyclohexene will polymerize quite readily giving high molecular weight cyclic products.[88]

Other Olefins. Activated floridin at 150-270°C. causes considerable isomerization of the tertiary butyl radical in the higher olefins. *ter*-Butylethylene underwent 47.4 per cent change to tetramethylethylene, and *unsym*-methyl-*ter*-butylethylene yielded 54 per cent of trimethylethylethylene. Neither of the products was affected by the floridin.[89] This catalyst may also exert a depolymerizing effect on higher olefins. At 50°C., triisobutylene begins to break down, and at 180° to 190°C. the decomposition is complete, 99 per cent being dissociated to diisobutylene and isobutene and the remainder to isobutane and octene. At the same time, part of the diisobutylene is repolymerized to form the tetramer and higher forms.[90]

To a small extent, pinene vapor is polymerized to polyterpenes at 330°C. in the presence of copper, nickel, cobalt and iron. The principal reaction at this temperature, however, is one of isomerization.[91]

POLYMERIZATION OF OLEFIN MIXTURES TO AROMATICS, AND LOW-BOILING LIQUID OLEFINS

Birch and Hague obtained yields of 5 per cent of styrene, 2 per cent of indene and some butadiene and cyclopentadiene by polymerization of the gaseous olefins resulting from the pyrolysis (at 850°C. and 20 lbs. per sq. in. pressure) of a still gas containing mainly methane, ethane, propane and butane. Styrene was believed to result from the union of ethylene and benzene, and subsequent dehydrogenation, as:

$$C_6H_6 + C_2H_4 \longrightarrow C_6H_5C_2H_5 \longrightarrow C_6H_5C_2H_3 + H_2$$

Indene may be formed by the combination of propene and benzene or toluene and ethylene, followed by ring closure and elimination of hydrogen, similar to the above reaction, or by demethanation of dicyclopentadiene:

Dehydrogenation or demethanation account for the formation of butadiene and cyclopentadiene.[92] Dunstan, Hague and Howes reported high yields of liquids by polymerizing ethylene hydrocarbons obtained from the thermal decomposition of mixtures of the lower paraffins. Polymerization was carried out in an autoclave at 100 atmospheres pressure and 380° to 410°C. In addition to styrene, indene and the diolefins mentioned above, benzene, toluene, *m*- and *p*-xylene, naphthalene, anthracene, phenanthrene and chrysene were produced.[93]

Low-boiling unsaturated liquids are formed by passing an "ethylene concentrate" (a mixture of lower olefins) through a quartz tube charged with silica gel and heated to 550-580°C. at atmospheric pressure.[94] An increase in temperature causes a higher yield of benzene at the expense of the olefins. Under pressure and at 320° to 360°C., using zinc chloride as the catalyst, the products are quite different, consisting of paraffins, aromatics, naphthenes and olefins, although the latter do not exceed 30 per cent in this case.

Both liquid products and acetylene may be recovered from waste gases such as those obtained in oil cracking, according to Morrell,[95] who recommends a three-step process. First the gas mixture is pyrolyzed at 800-1200°C. at reduced pressure and contact times of less than 0.10 second, to form high yields of olefins. The second step involves polymerization of these unsaturates (principally the propene and higher members of the series) to liquids by means of a phosphoric acid catalyst. The residual gases from this treatment (mostly ethylene) are now heated to about 1100°C., under reduced pressure, for about 0.10 second to produce acetylene. Morrell cites as an example a stabilizer gas containing 25 per cent methane, 23 per cent ethane, 18 per cent propane, 12 per cent butane and higher paraffins, 5 per cent hydrogen and 17 per cent olefins. This material was cracked at 900°C. and 50 mm. pressure for 0.01 second, and the resulting olefins polymerized at 400°F. and 100 lbs. per sq. in. pressure. The liquid obtained netted 3 gallons of gasoline per 1000 cu. ft. of input gas. The residual gas, heated to 1400°C. at a pressure of 50 mm. for 0.06 second gave 450 l. of acetylene per 1000 l. of the original stabilizer gas.

Ipatieff and Nemtzov[96] found that polymerization of mixtures of the lower olefins, such as ethylene and propene, was greatly influenced by the presence of hydrogen, since under these conditions a product resulted which boiled almost entirely below 200°C. Evidently, polymerization under these conditions is accompanied by hydrogenation to the corresponding paraffins. As a matter of fact, mixtures of ethylene and a large excess of hydrogen treated in a similar manner were found to give no liquid products, showing that hydrogenation predominated over polymerization. Although the gas mixture underwent polymerization above 350°C., it appears that saturation of the olefins occurs at much lower temperatures. Above 440°C. cracking begins to take place, as is shown by the deposition of carbon on the walls of the reaction vessel. Activated carbon and alumina were ineffective as catalysts. The carbonaceous material promoted the condensation reactions, however. The optimum conditions for the production of low-boiling liquid products are reported as a temperature slightly above 400°C. and a hydrogen pressure of 300 atmospheres.

STYRENE AND OTHER ARYL SUBSTITUTED OLEFINS

Polystyrene, a highly polymerized form of styrene, may be produced by heating the latter with about 2.5 per cent of benzoyl peroxide. Yields of about 34 per cent have been obtained by Natelson, using this method.[97] Staudinger and Steinhofer[98] found by heating polystyrene for 6 hours at 310-350°C. and atmospheric pressure, it underwent depolymerization, giving 62.5 per cent styrene, 19.2 per cent distyrene, 3.8 per cent tristyrene, no tetrastyrene and 9.6 per cent residue. At 290 to 320°C., under reduced pressure, and with a 12-hour heating period, the yield of styrene was reduced, amounting to only 38.4 per cent. The dimer was present in the same proportion as in the first case (19.2 per cent), however, the amounts of tristyrene, tetrastyrene and the residue were increased to 23.0, 3.8 and 11.4 per cent respectively. These investigators reported that the dimer consisted of 1,3-diphenyl-3-butene and 1,3-diphenylpropane, while the trimer was composed of 1,3,5-triphenyl-5-hexene and 1,3,5-triphenylpentane. Polymerization of styrene is apparently a chain process, interrupted by a secondary change which occurs with increasing frequency as the rate of polymerization increases.[99]

From their studies of the properties, mechanism of formation and constitution of the polymers of styrene obtained using various catalysts, Risi and Gauvin[100] have advanced a theory pertaining to the nature of the secondary change noted by Staudinger and Steinhofer. After standing for several days in the dark with antimony pentachloride in benzene solution, styrene formed a resinous mass which was separated into 2 polymers, one melting at 60°C. and having a molecular weight of 636 and the other with a molecular weight of 1335 and a melting point of 90° to 92°C. Both substances were saturated, as was shown by their inability to add bromine. Similar saturated polymers were also isolated from polystyrene prepared by the method of Staudinger and Steinhofer[101] (using sulphuric acid as catalyst) and from Fittig-Erdmann[102] distyrene (1,3-diphenylbutene-1) when polymerized by means of stannic chloride. On the other hand, the distyrene of Stoermer[103] (2,4-diphenylbutene-2) was not affected by the latter catalyst, from which Risi and Gauvin suggest that this hydrocarbon is likewise completely saturated. These investigators also agree with Staudinger and Steinhofer in that the polymerization reactions are of the chain type and do not take place by stages. The secondary transformation which is believed to check the polymerization involves the cyclization of the intermediary unsaturated polystyrene into a saturated filamentary molecule terminated by a hydrindenic ring. This may be represented graphically for the dimerization by the reaction:

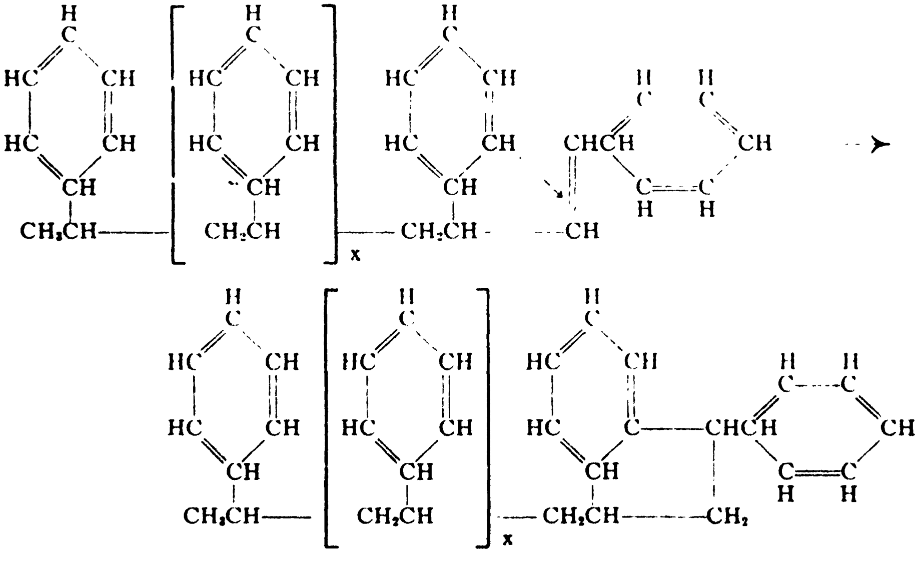
Higher polymers may also be explained according to this system:



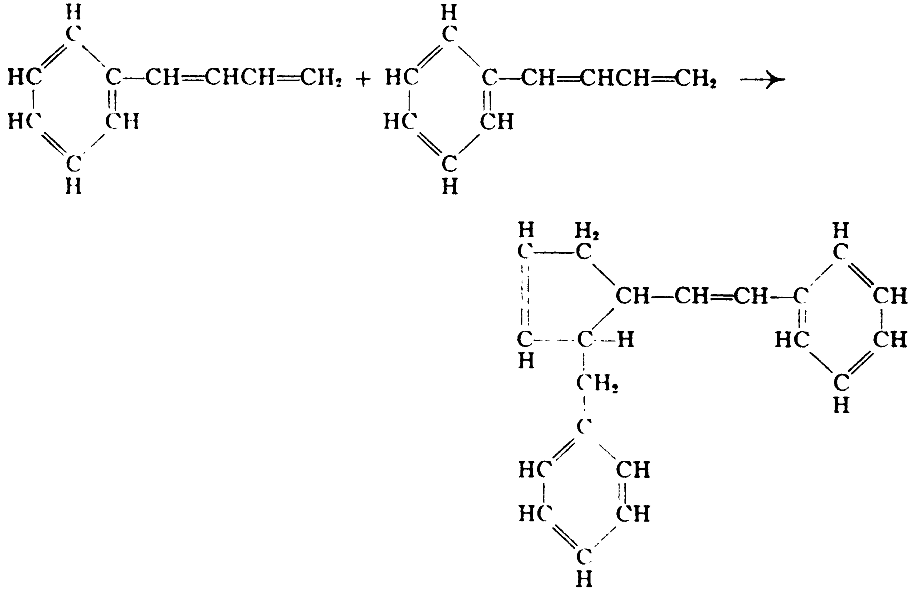
In contrast with the ease of combination of styrene molecules, propenylbenzene derivatives polymerize with difficulty, and only in the presence of catalysts. The introduction of a terminal methyl group diminishes the tendency of the ethylenic linkage toward combination to form complex molecules. Polymerization of propenylbenzene follows a chain mechanism with the linkages occurring in the 1,3 position (instead of the 1,2, as with other ethylenic compounds). This is probably due to the mobility of the hydrogen in the methyl group of the allyl radicals.[104]

---

[104] H. Staudinger and E. Dreher, *Ann.*, 1935, 517, 73; *Chem. Abs.*, 1935, 29, 4336; *Brit. Chem. Abs.* A, 1935, 740.

Staudinger and Dreher polymerized propenylbenzene in toluene solution by means of boron trifluoride, the latter giving products having a molecular weight up to about 2000. Cracking of the polymer gave rise to diphenylbutadiene and propylbenzene.

Bergmann[105] found that 1-phenylbutadiene dimerizes to form 2-benzyl-1-styryl-3-cyclopentene. This result is explicable if the process is assumed to follow a course similar to that of the simple ethylenes[106] involving the formation of an open chain hydrocarbon by displacement of one hydrogen in the methylene group. Migration of one of the double bonds leads to the formation of a conjugated system in which one of the hydrogen atoms becomes activated and migrates with the formation of a five-membered ring, as for instance:



Phenylated olefins may be cyclicized into the corresponding tetralins or indanes by treating with 85-90 per cent sulphuric acid as a catalyst.[107] However, polymerization also occurs to a greater or less degree even with alcohols, which are dehydrated to the corresponding olefins in the presence of this promoter. Thus, 20 cc. of 1-phenylpentanol-1 (butyl phenyl carbinol) was added slowly, with constant stirring, to 30 cc. of 90 per cent sulphuric acid at 9 to 10°C. The olefin formed, 1-phenylpentene-1, was completely polymerized to a substance boiling at 163-165°C. at 2 mm. pressure. Similarly, 1-phenyl-2-methylpentanol-2, 3-phenylpropanol-1, 4-phenylbutanol-2, 4-phenyl-2-methylbutanol-2 and 4-phenylbutene-1 underwent considerable condensation with this catalyst.

DIOLEFINS

Allenes. Activated floridin causes a partial polymerization of hydrocarbons of the allene series. Methyl allene (1,2-butadiene) is polymerized to the extent of 22 per cent by passage over this catalyst at 245°C. and 25 per cent at 330°C. Dimers of methyl allene and also of bivinyl, the chief isomerization product,[108] could not be identified in the resulting polymers.[109] In the case of *unsym*-dimethyl allene [$CH_2{=}C{=}C(CH_3)_2$], however, the chief polymerization product was the dimer of isoprene. In fact, at temperatures above 334°C. using floridin activated at 325°C., the content of isoprene in the pyrolysis mixture remained unchanged, because the velocity of its formation is equal to that of its polymerization.[110]

Butadiene. The kinetics and mechanism of the thermal polymerization of 1,3-butadiene at 400-700°C. and atmospheric pressure were studied by Moor, Strigaleva and Shilyaeva.[111] Results of experiments made in a copper coil and a vertical porcelain tube indicate that at 400°C. the primary thermal reaction is bimolecular and may be represented by:

$$2C_4H_6 \longrightarrow C_8H_{12}$$

By polymerizing at 450-700°C. products of both higher and lower boiling points than butadiene are obtained. The change of surface has apparently no effect, as the two methods produced substantially equal results. The energy of activation under these conditions is given as 28,000 cal. per mole, while the variation of the rate with temperature is given by the expression:

$$\log_{10} k = 7.32 + \frac{6400}{T}$$

Rubanovskii used the glow discharge method to investigate the kinetics of butadiene polymerization.[112] At 0.001 to 0.1 mm., the pressure in the discharge tube increases to what corresponds to the cracking of butadiene, whereas above 0.1 mm. the pressure decreases because of the contraction in volume in the polymerization of the hydrocarbon. During discharge, in a mixture of hydrogen and butadiene, the shock impact of the hydrogen atom also is believed to induce polymerization. The chain character of the mechanism is indicated by the induction period (3 to 7 minutes, which is typical for this type of reaction). The acceleration of the rate of reaction by dilution with argon and oxygen, which hampers the diffusion and breaking of chains on the sides of the tube, further suggests the chain mechanism. In addition, the speed of polymerization is much greater in a larger tube. The kinetics of the process are not affected by the characteristics of the discharge nor by the material of the electrodes.

The thermal polymerization of liquid butadiene at 110-200°C. has been reported by Lebedev and co-workers to be a homogeneous reaction, greatly catalyzed by the presence of oxygen. The energy of activation for the liquid phase treatment is 13,000 cal. On the other hand, in order to have the reaction proceed in the gaseous phase over the same temperature range, an energy of activation of 25,000 cal. is required.[113]

Heating at 150°C. for 120 hours converts butadiene into a dimer, consisting mainly of 1-ethenyl-3-cyclohexene and a small amount of 1-ethenyl-1-cyclohexene. No open chain dimerides are formed, and there is no tendency to further polymerization.[114] Slobodin also reports the formation of 1-ethenyl-3-cyclohexene by heating butadiene to 400°C. in the presence of a dehydrogenation catalyst.[115] The dimer, 1-ethenyl-3-cyclohexene, is said to be the chief resultant of the thermal polymerization of butadiene in the presence of nitrogen at temperatures of 250 to 400°C. However, with long periods of contact, especially at high temperatures, hydrogen and methane were also formed, indicating decomposition of the polymers.[116] The addition of copper naphthenate or oleate in small percentages (0.001 to 0.41 per cent of copper) has been suggested to restrict the polymerization of butadiene to the dimer stage alone.[117] After heating butadiene for 29 days at 80°C. in the presence of 3.20 per cent of copper naphthenate (0.407 per cent copper), 45.87 per cent of dimer, but no higher polymers resulted. Metallic copper acts in a similar manner, but is less effective. Although an increase in the concentration of either copper or its salts increases the effectiveness for prevention of higher polymers, the dimerization reaction is stated to proceed independent of the concentration of the inhibitor.[118]

Diazoaminobenzene has been suggested as a catalyst for polymerizing butadiene in the Russian synthetic rubber industry.[119] The process is carried out at 100°C. under 18-20 atmospheres pressure with constant stirring. Another catalyst which may be used for the polymerization is metallic sodium. However, it has been pointed out that the technical butadiene obtained from petroleum does not undergo polymerization with sodium because of the destruction of this catalyst by the admixed impurities.[120] The use of an alkali metal, such as sodium, in conjunction with an unsaturated ether (vinyl ethyl ether), is also recommended.[121] The polymerization of butadiene with sodium in an atmosphere of carbon dioxide has been investigated by Koblyanskii and Rokityanskii,[122] who report that under these conditions, the rate of polymerization is greatly retarded and a different type of polymer formed. The reaction product is described as a white porous substance, insoluble in benzene, chloroform and ether, containing 88.67 per cent carbon and 11.04 per cent hydrogen. It is stated to be autocatalytic to the polymerization reaction and also to oxidize quite rapidly on exposure to air. Alkali organic compounds of the type of sodium triphenylmethyl and sodium diphenylmethyl also catalyze polymerization.[123]

A method of removing butadiene from cracked gases has been suggested by Odell.[124] The gas mixture (such as refinery gas) is preheated to 300-800°F., mixed with hot combustion gases and about 0.5 per cent oxygen, 10 per cent steam and a small amount of sulphur dioxide and then passed over a bed of solid refractory material. The contact mass ordinarily employed is fire brick, into which may be also incorporated substances of a promoting nature, such as aluminum phosphate, iron oxide or aluminum oxide. The polymerization of butadiene and other unstable diolefins is said to be complete in about 1 to 5 seconds at temperatures of 600-1400°F. and pressures of 50 to 175 lbs. per sq. in. with this treatment.

Cyclopentadiene. The kinetics of the polymerization of cyclopentadiene have been investigated by Khambata and Wassermann[125] and Kistiakowsky and Mears.[126] The results of Khambata and Wassermann show that the reaction when carried out in a benzene solution at 15 to 55°C. is bimolecular.[127] Kistiakowsky and Mears studied the dimerization using tetrahydronaphthalene as solvent and also found the transformation to be of the second order, with about the same absolute rate as that in benzene solution. However with pure liquid cyclopentadiene, the latter authorities report that the order decreases, the reaction being nearly of the first order kinetically, with an activation energy of 17,300 cal.[128] In neither investigation was evidence obtained to indicate a chain mechanism for the dimerization.

The constitution of the polymerization products of cyclopentadiene is of a very complex nature. Pirsch supported the Diels and Alder theory[129] which postulates the formation of polymers of the isocamphene type. These conclusions were based on determinations of the molecular melting point depression of the various derivatives.[130] However, Alder and Stein[131] showed that the evidence of this nature was insufficient to prove the problems of structure and configuration. The latter investigators point out that the differences between the heats of hydrogenation of the various compounds could be due either to a strain in the molecule or to the particular structure of the bridged ring.[132] The later work of Alder and Stein[133] shows that the formation of these polymers consists of two reactions, first of the partial 1,4 addition of two conjugated unsaturated molecules and secondly of the addition of a conjugated system at the isolated double bond of the reaction product of the first stage as shown in reactions (1) and (2), respectively, on page 653. Thus, every one of the polymers is capable of adding another molecule of cyclopentadiene, and the formation of a continuous series of homologues is limited only by physical properties, according to Alder and Stein. For instance, the solubility of the polymers begins to decrease so rapidly at the tetracyclopentadiene that the polymerization is practically finished with the heptacyclopentadiene.

Barrett and Burrage[134] have measured the change in vapor pressure of the system during the polymerization of cyclopentadiene. From the vapor pressure-composition curve of known mixtures of cyclopentadiene and its dimer, the course of the reaction could be followed. After 93 days, at 12°C., the dimerization was

[125] B. S. Khambata and A. Wassermann, *Nature*, 1936, **137**, 496; *Brit. Chem. Abs.* **A**, 1936, 684; *Chem. Abs.*, 1936, **30**, 4078.

[127] A. Wassermann (*Nature*, 1936, **138**, 369; *Chem. Abs.*, 1936, **30**, 7431) has reported that the reaction when carried out in paraffin solution is also bimolecular.

[128] According to B. S. Khambata and A. Wassermann (*Nature*, 1936, **138**, 368; *Chem. Abs.*, 1936, **30**, 7431), the decomposition of dicyclopentadiene to give cyclopentadiene is unimolecular both in paraffin solution and in the pure liquid state.

(2)

99.27 per cent. The transformation is apparently complete after one year. The refraction analysis method of Stobbe and Reuss[135] for determining the rate of polymerization (which is based on the simple dimerization process) has been proven to be in error by the work of Terent'ev and Solokhin.[136] Polymerization of the dimer to higher polymers causes increased values in the observed refractive indices. The disregard of the latter reactions causes considerable error in the degree of polymerization indicated by the refractometer observations.

POLYMER GASOLINE

Because of the increasing demand for high octane gasoline and the simultaneous recurring fear that crude oil supplies may become exhausted, much interest has been shown in the potential supply of motor fuel made possible by the polymerization of olefins. The requirements for greater quantities of gasoline were at first largely filled by the cracking process. Egloff[137] has pointed out that in 1934, cracking (of gasoline and heavy oil) supplied 300 billion cu. ft. of gases, one-sixth of which were olefins that could be polymerized to over 1 billion gal. of gasoline having an octane number of about 81. An additional 2 billion gal. of motor fuel of the same quality could be obtained by dehydrogenation and subsequent polymerization of the deolefinized gas. Refinery gases (from the distillation of crude oils) represented another billion gal. of potential gasoline had the propene and butane been dehydrogenated and polymerized, while the natural gas and gasoline industries added another 5 billion gal. in the form of propane and butane. Thus, the total polymerized gasoline potentially available in the United States alone in 1934 was over 9 billion gal. or about 50 per cent of the total gasoline consumed. The amount of crude oil required to produce the 1934 demand for gasoline would have been reduced to 60 per cent of its volume had this potential supply of polymer gasoline been utilized; or 360,000,000 barrels of crude oil could have been conserved in that year.

In addition to its high antiknock rating, polymer gasoline has a high octane blending value.[138] Comparison of these characteristics with those of benzol and isooctane are given in Table 137.

TABLE 137.—*Octane Ratings and Blending Values of Polymer Gasoline.*

	Octane Rating	Blending Value
Polymer gasoline	81	103-125
Benzol	97	84-91
Isooctane	100	94-99

There are two general divisions for the processes available for this type of polymerization,[139] one purely thermal, and the other catalytic. The first method utilizes still gases or natural gas and is essentially a two-step process, cracking the gas to olefins and subsequent polymerization of the latter by application of heat and pressure. The second procedure involves only polymerization of unsaturated hydrocarbons at relatively low temperatures and pressures in the presence of an accelerator, such as phosphoric acid.

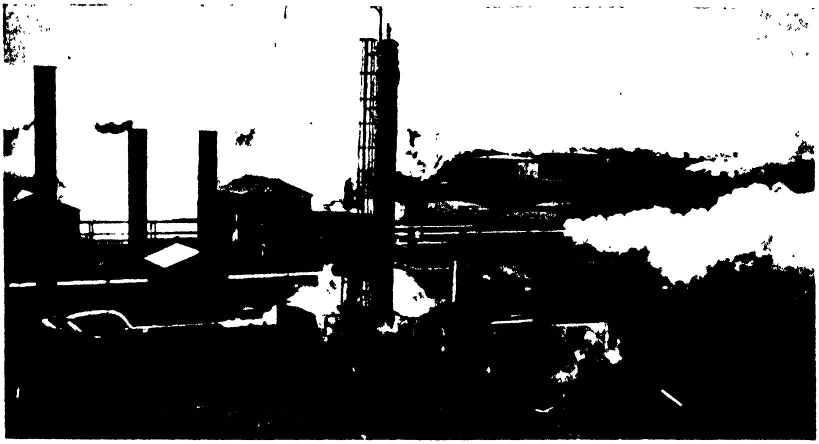
Thermal Processes for Production of Polymer Gasoline. In the thermal process, either of two sets of conditions is usually practiced, low temperature-high pressure or high temperature-low pressure treatment.[140] Under the first set of conditions, below 800°F. (425°C.) and 500 to 3000 lbs. per sq. in. (35 to 200 atmospheres) pressure, straight chain hydrocarbons dominate in the product. The latter conditions [above 1000°F. (540°C.) and pressures less than 200 lbs. per sq. in. (about 15 atmospheres)] result in a liquid which is almost entirely aromatic in character.



Courtesy Pure Oil Co

FIG. 143.—Small Commercial Polymerization Unit.

Thermal polymer gasoline may be produced in any one of three methods, one-, two- or multi-stage, depending upon the composition of the feed gas. The one-stage process may be used with gases high in olefins, which can be polymerized directly, or simultaneous cracking and polymerization may take place, as in the so-called Unitary Process considered later in this chapter. In the case of gases with a high paraffin content, cracking is always necessary, so that a two-step method is employed in general. The multi-stage process is used only with gases having a large concentration of propene and butenes along with lower paraffins. The olefins are removed first by condensation, the remaining paraffins cracked in a second operation, and the resulting olefins are polymerized in a third step.

Chem. Abs. **B**, 1936, 435. C. O. Willson, *Oil Gas J.*, 1935, **33** (50), 16, 44; *J. Inst Pet. Tech.*, 1935, **21**, 307A; *Chem. Abs.*, 1935, **29**, 6019. *Petroleum Times*, 1936, **35**, 533; *J. Inst. Pet. Tech.*, 1936, **22**, 306A.

[140] Discussions of these processes are given by C. R. Wagner, *Ind. Eng. Chem.*, 1935, **27**, 933; *Chem. Abs.*, 1935, **29**, 6747; *J. Inst. Pet. Tech.*, 1935, **21**, 377A; *Brit. Chem. Single-Stage Polymerization. Gases rich in olefins, such as those from vapor-phase cracking of hydrocarbon oils, may be polymerized directly to liquid fuels. Either high pressure-low temperature or high temperature-low pressure treatment may be employed. The yield of distillate is somewhat greater in the former case when operating on the same charging stock.[141]

Using the high pressure method, a flow sheet of which is given in Fig. 144, the gases are compressed to 600-800 lbs. per sq. in. pressure and heated to 900-1000°F. in a pipe-coil heater.[142] The gas is passed into a reaction chamber, ordinarily in the form of a coil which is cooled in order to absorb the exothermic heat of reaction[143] and is then chilled by injection of either cold gas or oil. Reaction is checked at about 60-70 per cent conversion. The product is then fractionated and the distillate stabilized, giving a yield of gasoline of 3.25 to 4.5 gal. per 1000 cu. ft.

The stock may also be charged in the liquid phase, which permits the elimination of low-molecular weight paraffins. The variation has several reported advantages, such as lower power costs due to removal of the inactive gases and a uniform control of polymerization reactions. Some tar-formation is traceable to the presence of ethylene since this olefin gives rise to such bodies at the operating temperatures required with propene-butene mixtures. However, the gasoline yield is only slightly reduced by the tar formation.

[142] Plummer recommends the use of a preheating zone with low-content olefin gases (W. B. Plummer, U. S. P. 1,947,306, Feb. 13, 1934, to Standard Oil Co. of Ind.; *Chem. Abs.*, 1934, **28**, 2367; *Brit. Chem. Abs.* **B**, 1934, 1048). The use of pressures up to 3500 lbs. per sq. in. is reported by M. P. Youcher, U. S. P. 1,976,469, Oct. 9, 1934, to Phillips Petroleum Co.; *Chem. Abs.*, 1934, **28**, 7517; *Brit. Chem. Abs.* **B**, 1935, 794. See also R. F. Ruthruff, Canadian P. 345,542, 1934, to Standard Oil Co. of Ind.; *Chem. Abs.*, 1935, **29**, 2338.

[143] The problem of absorbing the exothermic heat of polymerization has been discussed by C. R. Wagner (*Ind. Eng. Chem.*, 1935, **27**, 933; *Chem. Abs.*, 1935, **29**, 6747; *J. Inst. Pet. Tech.*, 1935, **21**, 377A; *Brit. Chem. Abs.* **B**, 1935, 887. Proposals for the utilization of this heat, such as for preheating feeds, are given by R. Ruthruff (U. S. P. 2,038,086, Apr. 21, 1936, to Standard Oil Co. of Ind.; *Chem. Abs.*, 1936, **30**, 3834; *J. Inst. Pet. Tech.*, 1936, **22**, 264A). F. W. Sullivan, Jr., U. S. P. 2,031,987, Feb. 25, 1936, to Standard Oil Co. of Ind.; *J. Inst. Pet. Tech.*, 1936, **22**, 263A; *Chem. Abs.*, 1936, **30**, 2743. W. B. Plummer, U. S. P. 1,991,353, Feb. 12, 1935, to Standard Oil Co. of Ind.; *Chem. Abs.*, 1935, **29**, 2348; *Brit. Chem. Abs.* **B**, 1936, 87. R. E. Wilson, Canadian P. 345,537, 1934 and W. B. Plummer, Canadian P. 345,538, 1934, both to Standard Oil Co. of Ind.; *Chem. Abs.*, 1935, **29**, 2340. W. B. Plummer and V. Voorhees, U. S. P. 1,991,354, Feb. 12, 1935, to Standard Oil Co. of Ind.; *Chem. Abs.*, 1935, **29**, 2348; *J. Inst. Pet. Tech.*, 1935, **21**, 174A; *Brit. Chem. Abs.* **B**, 1936, 87.

Table 138 summarizes typical data obtained in one-step polymerization processes under both high and low pressure treatment.[144]

Polymerization may be effected in the presence of an inert liquid medium, such as paraffin oil, at 300-500°C. under 20 to 50 atmospheres pressure.[145] Sullivan and Ruthruff[146] propose to employ a continuous system, using naphtha or gas oil as the solvent under 500 lbs. per sq. in. pressure and 650°F. Good yields of gasoline having a good antiknock rating are reported using this treatment.

The removal of hydrogen and methane from the feed gas may be accomplished in several ways. Ruthruff, Roberts and Carpenter[147] suggest the concentration of dilute olefin gases by scrubbing with liquid butane (under pressure) below 100°F. The absorbed gases are released from the butane solution by heating to 125-350°F. under 350-500 lbs. per sq. in. pressure, and subjected to polymerization. The liquid polymerization product may also be used for concentrating the feed gas. Plummer prefers to pass the liquid and gaseous products at a pressure of 500-3000 lbs. per sq. in. into a separator and introduce dilute olefinic gases through the liquid. The undissolved fixed gases are removed at the top of the separator and eliminated. The liquid and dissolved gases are withdrawn, the pressure released, and the concentrated olefinic gases introduced directly into the heating zone.[148] The gas mixture may also be subjected to pressures of about 1000 lbs. per sq. in. to liquefy hydrocarbons higher than methane. The uncondensed gases are thereby eliminated.[149]

Plummer suggests the use of two complementary treatments. Rich olefins are subjected to a relatively low temperature (370-510°C.) while lean gases are treated at higher temperatures (510-675°C.), in separate units, at pressures of 500 to 3000 lbs. per sq. in. The liquid products are separated and from the first system a lean olefinic gas is obtained, while the second gives a gas rich in unsaturates. These gases are then recycled to the respective high and low temperature systems.[150]

The Unitary Process. One method of thermal polymerization, the so-called Unitary Process, has been studied by Keith and Ward.[151] According to these investigators, thermal polymerization and cracking occur simultaneously in this process, and under the proper conditions, the specific rates of reaction are controllable and direct conjugation of saturates with unsaturates can be brought about.

FIG. 145.—Flow Diagram of Unitary Process. (J. T. Ward)

The charging stocks may vary from natural or refinery gases to the complex mixtures found in stabilizer reflux or absorber oil distillates. Separation of the paraffinic and olefinic hydrocarbons is normally not required. The yield and nature of the product will vary according to the composition of the feed stock, a highly unsaturated gas (70 per cent) giving a liquid lower in specific gravity, lower in paraffins and higher in aromatics than a low olefin content feed gas (one containing only 15 to 35 per cent unsaturates). A yield of 14 gal. of liquid with a blending value[152] of 80 to 120 is said to be obtained per 1000 cu. ft. of natural or refinery gas. The operating conditions are temperatures of 480 to 580°C. (900-1075°F.) and 800 to 2200 lbs. pressure. A flow sheet of this process is given in Fig. 145.

Two-Stage Process. Operations, involving combination of pyrolysis and polymerization steps, are described by Cooke, Swanson and Wagner.[153] They point out that gases from cracking stills of the so-called liquid-vapor phase type are particularly applicable as charging stocks. Using the high-temperature-low pressure polymerization treatment, the resulting gasoline is reported to contain 80 to 85 per cent aromatics and to have a knock rating of 100 octane number. Burk recommends cracking the gas at 1600-2100°F. (870-1150°C.), cooling to 1100°F. and then polymerizing at 1350-1750°F.[154]

Table 140 gives data obtained in a high-temperature operation using natural gas as the charging stock.

Frolich and Wiezevich[155] obtained the highest yield of liquids from propane by using a two-stage process with intermediate removal of hydrogen. They noted that in the pressure treatment of cracked gas there is a pronounced tendency for the hydrogen present to saturate ethylene and propene, thus decreasing liquid formation. Table 141 gives their results using a simultaneous cracking-polymerization operation, a two-step process, and a special method in which the hydrogen was removed previous to the polymerization step by heating with copper oxide for 2 to 5 seconds at 300-350°C.

Copper oxide treatment removed 90 per cent of the hydrogen, with only a small loss of olefins, and the high pressure method could be used to advantage.

Frolich[156] has also suggested the use of metallic copper as a catalyst for oxidizing the hydrogen to water. Thus, a typical cracked propane gas (39 per cent olefins, 31 per cent lower paraffins and 30 per cent hydrogen) was mixed with 15 per cent of oxygen and passed over copper shot at 400°C. The exit gas from this treatment contained substantially no free hydrogen. The material was dried, compressed to 600 lbs. per sq. in. and heated at 525°C. for 30 minutes, giving a yield of 4.56 gallons of liquid per 1000 cu. ft. of propane originally charged.

TABLE 141.—*Cracking and Polymerization of Propane.*

	Polymerization Conditions		Gallons per 1000 cu. ft.

Two-Step with intermediate hydrogen removal	400	2500	7.75	5.73
	400	600	—	4.56

White and Frolich[157] have reported that nickel, tin and iron and their oxides could also be substituted as catalysts in place of copper. When the above mentioned metals are employed, temperatures of 300 to 450°C. are said to be most effective. However, with the metallic oxides, much lower temperatures (ordinarily 200-350°C.) may be used. The presence of sulphur is objectionable, in that it poisons the catalyst. It is therefore customary to remove this element by scrubbing the gases with sodium hydroxide solution. White and Frolich found only small proportions (less than 1 per cent) of carbon monoxide and carbon dioxide in the hydrogen-free gas, showing that in the presence of the above catalysts, the oxygen combined with hydrogen in preference to carbon or hydrocarbons.

Another method of hydrogen removal is to add carbon monoxide prior to the polymerization step. Frolich[158] found that in the presence of a catalyst, consisting of nickel mixed with aluminum oxide, reaction between the carbon monoxide and hydrogen takes place at 200-350°C. under 100 atmospheres pressure. Frolich has also suggested using carbon dioxide in place of carbon monoxide. Nickel oxide, in finely divided form, likewise has a catalytic effect, especially if small amounts of thorium, chromium, vanadium, molybdenum, magnesium or boron oxides are added. According to Wiezevich and Whiteley,[159] the addition of small amounts of air or oxygen to the olefinic gases lowers the temperature and pressure required for polymerization. The oxygen is only necessary to initiate the polymerization reactions, and after once started, the condensation is said to run smoothly without further introduction of oxygen. These investigators prefer to heat the olefins to 200-400°C. at pressures of 10 to 200 atmospheres and then add 0.01 to 0.04 moles of oxygen. The reaction time is ordinarily in the magnitude of 8 to 10 hours. The product obtained by this treatment contains cycloparaffins, aromatics, higher olefins and some oxygenated compounds. Large proportions of oxygen, however, are said to have an adverse effect, causing the formation of large amounts of carbon, water and fixed gases.

[158] P. K. Frolich, U. S. P. 2,002,534, May 28, 1935, to Standard Oil Development Co.; *Chem. Abs.*, 1935, 29, 4373; *J. Inst. Pet. Tech.*, 1935, 21, 266A.

Guyer[160] also advocates a two-stage treatment. Thus, olefinic gases are polymerized at pressures of about 500 lbs. per sq. in., and at the same time, in a separate unit, a paraffinic stock (consisting mostly of propane, butane and pentane hydrocarbons) is cracked at high pressures (about 1000 lbs. per sq. in.) and the products of the two stages combined and separated into liquid and gaseous phases. The gases are fractionated into a light portion (below butane), which is discarded, and a butane fraction, which is returned to the pyrolytic unit and mixed with the fresh paraffinic charge.

Three-Stage Process (Multi-Stage). A typical charging stock for this type of operation consists of the stabilizer overhead containing about 30 per cent unsaturates. By polymerizing as the initial step, there is a distinct advantage in that the propene and butene can be converted to gasoline under the most favorable conditions. Fig. 146 shows the various phases of operation.

In the primary polymerization step, the charge is heated to the proper temperature and enters the reaction coil which is designed to give the desired time-temperature effect. Cooling means must be provided to keep the temperature within the proper limits. Immediately after leaving the coil, the reaction products are chilled to stop any further reaction. The total overhead passes to a cooler and accumulator where the chilling medium, polymerized distillate and a portion of the gaseous constituents are condensed. The remaining vapors and gases from this stage are passed directly into the pyrolysis unit and subjected to treatment analogous to the two-stage methods previously mentioned.[161]

Fractional polymerization may be effected by special processing. Ruthruff suggests treatment in at least three stages at progressively lower pressures to bring about this purpose. After the first polymerization stage, the fixed gases, such as methane and hydrogen, are separated and eliminated from the system. The subsequent steps are regulated, as regards temperature and pressure, so as to produce maximum yields of liquids. Concentrated olefinic gases are returned to the cycle, but more dilute gases are treated in distinct systems under the most appropriate conditions.[161a] The most favorable conditions reported by Ruthruff are given in Table 142.

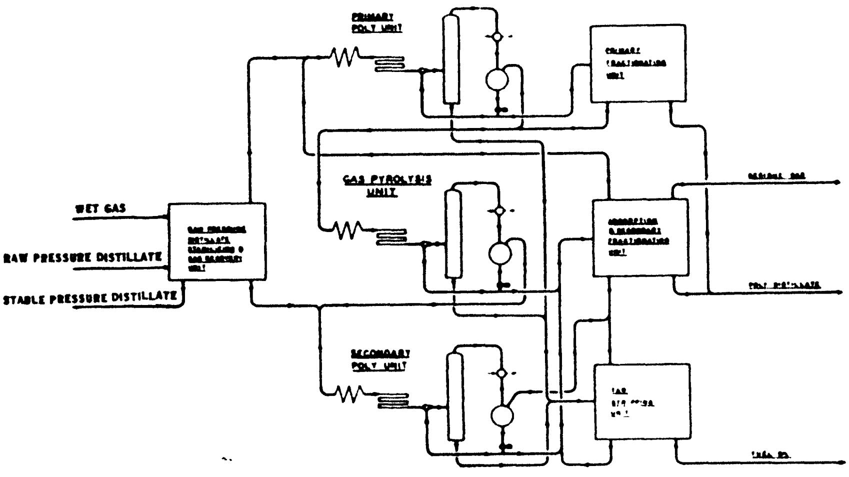
Catalytic Process for Production of Polymer Gasoline. This process may be defined as a method whereby cracked or dehydrogenated hydrocarbon gases are subjected to mild heat and pressure while flowing through a solid catalyst.[162] Using phosphoric acid as catalyst, relatively few types of polymers are produced so that the resulting liquid is of quite constant composition.



Courtesy Pure Oil Co.

FIG. 146.—Sketch of Three-stage Process of Polymerization.

The "solid" phosphoric acid catalyst,[163] consisting of phosphoric acid supported on an inert carrier, is generally used. The catalyst is prepared by mixing phosphoric acid (18 parts of 75 to 100 per cent phosphoric acid) with the carrier (7 parts) and calcining the resulting magma at 180-300°C. for 20 to 60 hours to remove most of the water. Supporting media which may be used are siliceous materials (such as kieselguhr, fuller's earth and bentonite), zinc or aluminum oxide and magnesium or calcium chloride. In addition, organic substances, for example, cellulose, starch, glue, gelatin and tar, may be incorporated to furnish a residue of carbon after calcining. In certain cases, to prevent the loss of water from the catalyst during operation, steam may be admixed with the olefinic gases.[104] Temperatures of 100 to 250°C. are advocated for this process. The catalyst is described as a hard non-corrosive solid whose action is not poisoned by carbon monoxide, hydrogen sulphide, mercaptans, or other constituents of refinery gases. Nevertheless, after protracted use, it becomes inactivated by contamination with high-molecular weight material. However, reactivity can be restored by mild oxidation (such as with air or oxygen) without removing the catalyst from its position in the contact towers.[105]

FIG. 147.—Flow Sheet of Polymerization Process Employing Solid Phosphoric Acid Catalyst. (G. Egloff)

A flow sheet of this process is given in Fig. 147. The feed, which may be gases from gasoline receivers, stabilizer tops or stabilizer reflux of cracking installations, cracking units or catalytic dehydrogenation units, is led to a pipe coil heater, which is maintained at 400°F. and a pressure of 200 lbs. per sq. in. The gas flows from the heater into a series of catalyst chambers or towers. A temperature rise of about 100°F. occurs in the catalyst bed due to the exothermic polymerization reaction. The polymer vapors pass through a cooling coil into a receiver, where the liquids are separated and stabilized.

Olefins are converted to liquid polymers, substantially of the monolefin type, by this treatment. Residual gaseous paraffins may be catalytically dehydrogenated and recycled over the catalyst as above. If the concentration of hydrogen sulphide in the feed gas is high, mercaptans will be formed during the polymerization, so the sulphides are generally removed prior to catalysis.[106] Over 75 per cent by weight of the original gaseous hydrocarbons can be converted to a gasoline of 81 to 83 octane number. The volume yield, based on a 50-50 propane-butane mixture, is over 19 gal. per 1000 cu. ft.[167]

[106] See Chapter 19 for a discussion of various methods for separation of mercaptans from hydrocarbons. See also Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., Inc., New York, 1934.

Ipatieff, Corson and Egloff have studied the effect of variations in temperature, pressure, rate of flow and the nature of the reacting gases.[168] The latter were from four sources, receiver gas, stabilizer reflux, stabilizer gas and commercial ethylene. The receiver gas was obtained in the liquid-vapor phase cracking (500°C., 200 lbs. pressure) of mixed Mid-Continent and West Texas topped crude. The stabilizer reflux was derived from stabilization of cracked gasoline from the above cracking treatment. The stabilizer gas came from stabilization of a gasoline from vapor-phase cracking of gas oil at 550°C. and atmospheric pressure. Results of various runs, along with comparative tests made on commercial ethylene (98 per cent ethylene and 2 per cent ethane) with the same apparatus are given in Table 143. From the results, it will be noted that the highest yield of total liquids was obtained from ethylene treated at 324°C. and 520 lbs. per sq. in. pressure with a gas velocity of 2.5 cu. ft. per hour per pound of catalyst. In this case, however, the proportion of gasoline in the product was less than 50 per cent. Shorter contact periods at the same temperature and pressure decreased the total quantity of liquids produced but increased the gasoline content to about 65 per cent. The highest percentage yield of gasoline was obtained using the most dilute olefin gas (receiver gas), 93 per cent of the total liquid boiling in the gasoline range (below 400°F.). The maximum yield of gasoline, 7.1 gal. per 1000 cu. ft. of gas, resulted from the treatment of stabilizer reflux at 232°C. and 100 lbs. per sq. in. pressure using the slowest gas velocity, 0.3 cu. ft. per hr. per lb. catalyst.

In addition to the solid phosphoric acid catalyst, Ipatieff has also suggested the use of aqueous phosphoric or phosphorous acids.[169] In this instance the olefinic gases are bubbled through the solution at 60° to 200°C. Polymerization of lower olefins by means of phosphoric acid may also be carried out in the presence of extraneous liquid olefins.[170] The reaction may also be brought about with low boiling liquid hydrocarbons by suspending phosphorus pentoxide in a solvent to which has been added a peptizing agent[171] (an organic compound containing a hydroxyl group, e.g., cresol). By thermally cracking natural and straight-run gasoline and polymerizing the olefins by means of phosphoric acid treatment, the antiknock properties of the fuel are said to be increased.[172]

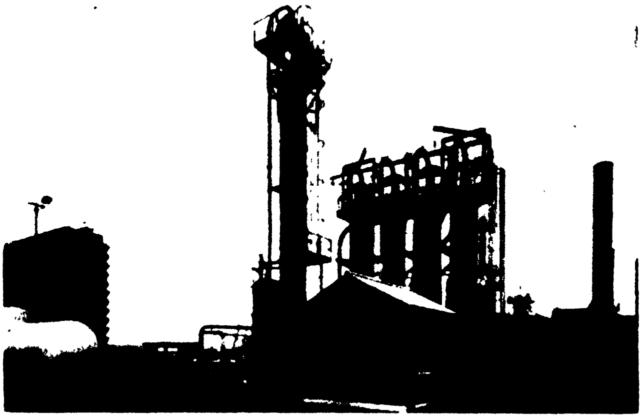
Other Catalysts for Producing Polymer Gasoline. Various metals have been proposed as catalysts. For example, olefins may be polymerized at 400-900°C. by conducting them over metal surfaces, coated or alloyed with tin, zinc, aluminum or chromium.[173] The use of platinum and palladium at 177-371°C. and 40 to 140 atmospheres pressure[174] and powdered zinc or iron oxide at low temperatures and high pressures[175] has been outlined. Burk proposes to employ the vapors of zinc or cadmium, or high-boiling salts, such as lead chloride, at temperatures above 700°C.[176] Volatile metallic halides, such as the chlorides of aluminum, nickel, iron, or titanium, or aluminum bromide, at 175-375°C. and 600 to 1500 lbs. per sq. in. pressure are recommended by Wagner.[177] An aqueous solution of hydrochloric acid in conjunction with brass is also said to exert a polymerizing action.[178]



Courtesy Industrial and Engineering Chemistry

FIG. 148.—View of Catalytic Polymerization Unit. Capacity 3 million cu. ft. of gas per day. (V. N. Ipatieff, B. B. Corson and G. Egloff)

Porous materials, having a large surface-volume ratio, are also applicable as contact agents. For example, Towne[179] employs adsorptive clays for this purpose. Gases containing 50 per cent of olefins (obtained from cracking of natural and refinery gases) are converted at 450° to 500°C. and pressures in excess of 1500 lbs. per sq. in. into straight chain polymers. Mixtures of acid-treated montmorillonite clay (200 mesh or finer) with 5-25 per cent of diatomaceous earth to reduce the resistance of the clay to the flow of vapors and gases have been described.[180] Wagner advocates the use of agents such as bentonite, silica gel, or activated charcoal. He attributes the catalytic properties of these substances to their selective adsorptive powers, which give local high concentrations of the unsaturated gases and thus promote specific polymerization reactions.[181]

REFINING OF CRACKED GASOLINE

An interesting and important phase of olefin polymerization is in the refining of cracked petroleum distillates. One of the problems in the storage and sale of cracked gasolines is the maintenance of its desirable properties, particularly in respect to color stability, antiknock properties and gum formation. The latter is associated with oxidation phenomena, especially in the case of diolefins containing conjugated bonds.[182] These hydrocarbons are markedly more unstable than monoolefins. Therefore, removal of such objectionable compounds is of considerable interest.[183]

The effect of high pressure, even up to 9000 atmospheres, on cracked gasoline has been discussed by Starkweather.[184] Treatment under these high pressures at 60°C. for 48 hours gave no indication of resinous products. However, 10 per cent of the low boiling constituents, mainly diolefins, were converted to higher boiling compounds.

Refining involving chemical treatment is usually necessary to effect removal of gum-forming constituents. Such operations may be carried out in the vapor phase, as for instance in the Gray and Lachman processes, or in the liquid phase, as exemplified by the method developed by Day (see below) and by the use of sulphuric acid.

Gray Process. Gray[185] proposed treatment of the hydrocarbon vapors with a solid adsorptive catalyst, such as fuller's earth. It was noted that, by this processing, diolefins and other unstable substances were polymerized to viscous oils or resinous solids while monolefins were practically unaffected. The volume loss was reported as less than 1 per cent. The procedure is said to be applicable also to gaseous olefins resulting in their polymerization to products boiling within the gasoline range.[186] In discussing the Gray process, Steininger[187] points out that a study of the factors influencing the treated material showed that rate of treatment, clay usage rate, the type of stock employed and the conditions of cracking affect the characteristics of the final product. Generally 5000 to 6000 barrels of refined distillate are obtained per ton of clay. Increased yields can be effected by use of higher pressures and temperatures with increased contact time.

A description of the Gray process has been given also by Mandelbaum.[188] He states that the best results are secured when operating near the dew point, so that the gasoline is in the vapor phase, but the polymers remain liquid. With increased pressure, efficiency of operation is improved.

Spent clay may be regenerated by roasting in a furnace at 900-1000°F. Clays of the fuller's earth type are considered best.[189] The use of copper oxide in conjunction with the clay is said to effect sweetening of the distillate and also to accelerate the removal of gum-forming constituents.[190] By mixing 5 to 25 per cent of a filter aid, such as kieselguhr, deeper beds of catalyst may be employed and better drainage of the polymers is said to result.[191]

A variation in the procedure, consisting in employing a two-step process, has been proposed. For example, gasoline is first treated in the vapor phase and then in the liquid phase with fresh adsorbent.[192] The fuller's earth may be kept in motion by a stream of gases of sufficient velocity to suspend the material in the heating zone.[193] Wells[194] suggested mixing cracked naphtha with a slurry of clay in gas oil under pressure. Thus, 5 to 20 per cent of the slurry (containing 1 to 4 per cent of clay and the remainder gas oil) is mixed with the crude naphtha, and passed through a tube heated to 350-600°F. The products are vaporized and fractionated, removing the gas oil and solid adsorbent clay while the naphtha is still maintained in the vapor phase. The purified material is subsequently condensed and the mixture of gas oil and clay is returned to the system.

Lachman Process. According to Lachman[195] this process consists in washing the hydrocarbon vapors with a hot concentrated solution of zinc chloride (50 per cent). The presence of large quantities of hydrogen sulphide adversely affects the operation. The vapors are usually stabilized before the treatment. In practice, the vapors to be treated, together with superheated steam, are passed countercurrent to the zinc chloride through a series of bubble towers.[196] The actual zinc chloride consumption ranges from 0.3 to 1 lb. per barrel of gasoline treated. The gasoline loss is reported as very low.[197]

Andreev proposed a variation of this method which involved the use of zinc chloride deposited on Raschig rings, pumice stone or gumbrin (a Russian clay).[198] Experiments on the refining of crude benzol and toluol in this manner were not very successful. However, it was pointed out that after this preliminary treatment with zinc chloride, 40 per cent less acid was required in the subsequent acid washing.[199] The use of pressure in conjunction with zinc chloride is advocated by Zadolin and Butkov.[200]

Day Process. This comprises treating hydrocarbons, in either the liquid or vapor phase, with aqueous hydrochloric acid in the presence of a free metal. Zinc, copper, aluminum, iron, tin and various alloys, such as brass, are used.[201] As an illustration of one mode of procedure, stabilized gasoline distillate is heated to the required temperature and charged into an acid-proof treating chamber, where it is mixed with dilute hydrochloric acid. The heated distillate and acid are contacted by upward flow through brass packing and then discharged into a fractionating column, where the polymers are separated. The distillate is neutralized with ammonia immediately after leaving the column. Polymerization losses of less than 1 per cent are reported, using this process.

Other Methods of Refining. As is well known, sulphuric acid has been used quite extensively as a refining agent, but since it will react with olefins, aromatics, naphthenes and even paraffins under certain conditions,[202] its use in this way is being more and more replaced by other substances which do not bring about such large losses in the purified product. Sager has listed the chief factors in the sulphuric acid operation as (1) concentration of acid employed, (2) amount of acid, (3) temperature at which the treatment is carried out and (4) the time of contact between the acid and oil.[203] Using 2 per cent by weight of concentrated sulphuric acid (98 per cent), the diolefins and most of the unstable olefins were removed in 5 to 25 seconds with intimate contact. Using more acid, the contact time could be reduced, and the inverse was true with smaller amounts of acid. The speed of polymerization of the olefins is rapid up to 80 seconds, but at 100 seconds can hardly be detected. The polymerization losses varied from 0.6 to 1.1 per cent for short periods and 1.8 to 5.5 per cent for the longer times. Sager found that chiefly the unsaturates were removed, the aromatics being only slightly affected, and the naphthenes and paraffins not at all during the above operations.[204]

De Florez[205] recommends the use of reduced pressure to effect cooling during the acid treatment. The more reactive gum forming constituents may be polymerized by the addition of a small quantity of acid, and can be withdrawn in the form of an acid sludge.[206] Ipatieff proposes to use acid sludge material from treating cracked products for refining. By interaction of the olefins and the acid sludge, alkylated compounds are formed, thus increasing the antiknock value of the gasoline.[207] By boiling kerosene with sulphuric acid, Ciochina also noted some degree of polymerization. In this instance oxidation occurred, as carbon was deposited, while with an excess of acid both carbon monoxide and dioxide were given off. The amount of high-boiling residue was considerably increased.[208]

Refining with adsorptive clay[209] may also be carried out in the liquid phase. Temperatures of 149-232°C. and 250 lbs. per sq. in. pressure or 315-370°C. and 1000 lbs. pressure are recommended for this type of treatment.[210] Dry copper silicate[211] can be substituted as contact agent in place of clay[212]

Molten selenium at 400-600°C. and 300 lbs. pressure[213] and sodium at 800-900°F. and reduced pressure[214] have been suggested as catalysts. Bruzac reports that the unstable constituents are polymerized readily by exposing the crude gasoline to sun or artificial radiations.[215]

Vapor phase refining may also be effected in a number of ways. Greensand[216] in the presence of hydrochloric acid or steam and hydrochloric acid, phosphorus pentoxide deposited on coke[217] and mixtures of clay and calcium oxide and sodium

[204] According to E. Wendehorst and E. Knoche (*Angew. Chem.*, 1934, **47**, 43; *Brit. Chem. Abs.* **B**, 1934, 179; *Chem. Abs.*, 1934, **28**, 2172) benzene is completely sulphonated by 100 per cent sulphuric acid after 1 hour's standing. Olefins, such as pentene, undergo partial sulphonation and partial polymerization, but paraffins and naphthenes are unaffected by this treatment. See also Chapters 46 and 50.

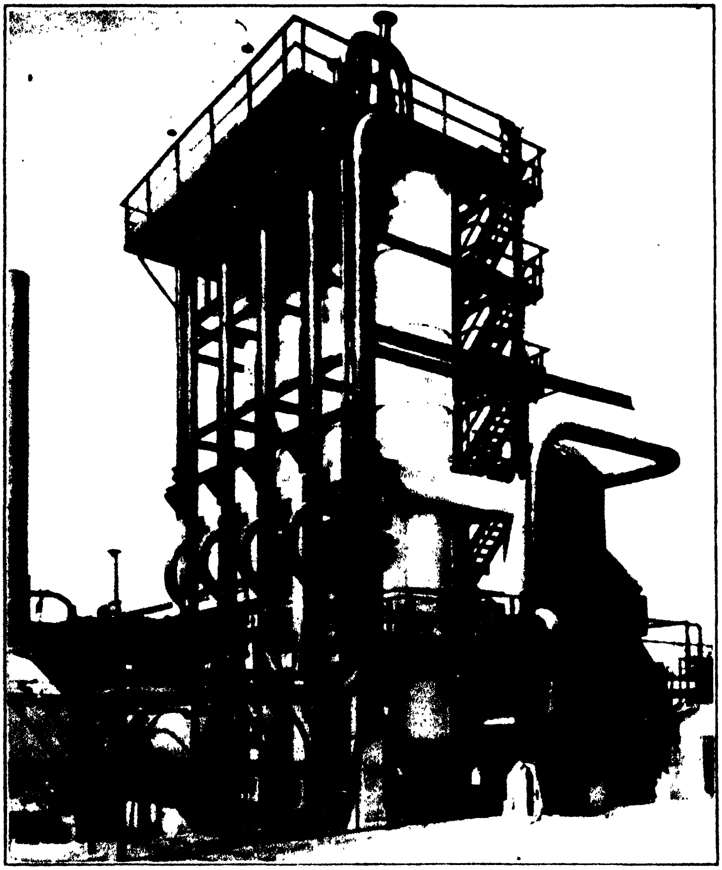
hydroxide[218] have all been investigated. Morrell[219] has advocated the use of heavy metal salts in the presence of a small amount of acid to prevent hydrolysis (e.g., ferric chloride and hydrochloric acid or zinc sulphate and sulphuric acid). Sulphonic acids, dissolved or suspended in inert organic mediums, may also be used as catalysts for the vapor phase treatment.[220]



Courtesy Universal Oil Products Co

FIG. 149.—Catalytic Polymerization Plant. Daily capacity, 8 million cu. ft. of gas.

Egloff reports that the addition of hydrogen to the hydrocarbon vapors under high pressure and moderate temperatures, in the presence of zinc chloride solution, produces a substantial saturation of the olefins in the cracked vapors.[221] This manner of treatment is reported to be effective for desulphurizing high sulphur-content oils, such as certain Mexican gas oils. Thus, Egloff suggests mixing the cracked gas oil vapors at 510°F. and 220 lbs. per sq. in. pressure with hydrogen and bubbling the gas through zinc chloride solution. Both hydrogenation and polymerization of the cracked vapors is said to result. Heat treatment with oxygen, under pressure, is also suggested to eliminate gum forming substances.[222]

SYNTHETIC LUBRICATING OILS

Another commercial application of polymerization is in the production of synthetic lubricants.[223] The work of earlier investigators[224] in this field indicated that lubricants obtained catalytically from ethylene had a very inferior viscosity-temperature coefficient. It was further established that the viscosity indices increased proportionally to the length of the straight carbon chain in the starting material.[225] Atkinson and Storch,[226] therefore, deemed it advisable to use a two-stage process, first thermally polymerizing the ethylene to a liquid boiling in the gasoline range and then further condensing this material with aluminum chloride to a viscous liquid of the "light" lubricant type. Thermal treatment was carried out at 370-395°C. and 50 to 70 kg. per sq. cm. pressure, and catalytic reaction was effected at room temperature with continuous agitation for 48 hours. The washed oil had viscosities of 155-208 seconds at 100°F. and 44-46 at 210°F. (Saybolt). Removal of the lighter ingredients (33 per cent) by vacuum distillation resulted in an oil with a viscosity of 532-710 seconds at 100°F. and 58.5-65 at 210°F. and a pour point of —20°F. Polymerization of ethylene at 100-300°C. and high pressure with a catalyst of aluminum chloride and aluminum has been reported to give products with viscosity indices of 60-70, whereas when aluminum chloride alone is used, the results are poor.[227] On the other hand, Koch has stated that synthetic material obtained using aluminum chloride at 130°C. is equal to, or better than, the natural product.[228]

Condensation of distillation products with aluminum chloride is generally carried out in two separate operations. In the first step, the more unsaturated hydrocarbons are polymerized to form a "mud" by means of the addition of a small amount of the catalyst. The remaining material is freed from this mud (by distillation or by means of solvents) and then subsequently treated with more of the catalyst.[229]

Wax-free lubricants may be obtained by the vapor-phase cracking of petroleum distillates.[230] For instance, at 540-700°C., gas oil yields a product which on redistillation has a viscosity of 200-600 seconds (Saybolt) at temperatures of 60° and 38°C., respectively.[231] Gaseous olefins may be converted to liquids of a viscosity index in excess of 100 by heating at 675° to 725°F. under 3000 lbs. per sq. in. pressure with heating times of 100 minutes or more.[232] Wiezevich and Whiteley recommend the addition of air in the treatment to form oxygenated products.[233] Lower olefins, such as ethylene, propene or butene, are preheated to about 310°C. under pressure, and mixed with small amounts of air. In addition to exerting a catalytic polymerizing action on the olefins, the oxygen is said to enter into combination with the polymers. Sulphuric acid, phosphoric acid,[233a] amines and other organic bases or nitrites[233b] have also been suggested as catalysts for the condensation. Olefins available for polymerization to synthetic lubricating oils are obtained by Loebel[233c] by cracking a paraffinic oil under pressure in the liquid phase, subsequently removing any resulting aromatic hydrocarbons and subjecting the remainder of the product to vapor-phase cracking.

SYNTHETIC RUBBER BY POLYMERIZATION OF BUTADIENE

Since 1930, the production of synthetic rubber by polymerization of butadiene has developed rapidly in Russia. Bridgwater[233d] has stated that 20,000 tons were produced in that country during the first ten months of 1935. In the entire year of 1934, the total output was only 11,300 tons. No information as to the cost is available, but it seems apparent from the yields quoted and statistics on the number of workers employed in the industry that the cost of the product is many times greater than that of natural rubber.

The butadiene used in this industry is derived by the pyrolysis of either petroleum fractions or ethyl alcohol.[233e] The first of these methods has been discussed by Buizov.[233f] In practice, the petroleum vapors are heated to 300-400°C., and then passed through a short heater, where cracking takes place at 700-800°C. and a pressure of 70-90 mm. The gases are expanded immediately after heating, then thoroughly cooled, liquefied by compression and fractionally distilled. Decomposition and condensation of the butadiene formed is avoided by the control of temperature, pressure and velocity of the vapors through the reaction zone. Yields as high as 16 to 17 per cent of butadiene are stated to be obtained in this manner. Table 144 shows the yield of products resulting when using raw materials on a semi-commercial scale under the above conditions.

TABLE 144.—*Products Obtained by Pyrolysis of Petroleum Fractions.*

Petroleum Fraction	Butadiene, %	Gas, cu.m./kg. Oil	Tar, g./kg. Oil
Crude Oil	10-11	1.10	—
Kerosene	11-12	0.67	150-180
Machine oil	11	0.68	150
Transformer oil	11	0.64	180
2nd grade gasoline	12-15	1.05	20
Naphtha	10	0.79	30
1st grade gasoline	15	0.75	70-90
Fuel oil	10	0.51	190

Butadiene may be separated from the other resultants by absorption in benzene, kerosene, absolute alcohol, water or gasoline, or by compression. Kerosene and water remove the most, but the former solvent may retain as much as 50 per cent of the hydrocarbon, which cannot be recovered. The compression method is reported as giving a stock of variable composition. Polymerization is carried out in autoclaves (lined with hard rubber) in the presence of 1 per cent of diazoaminobenzene as catalyst. Optimum conditions for this step are given as 100°C. and 18 atmospheres, and yields of 50 per cent of "butadiene rubber" are obtained after 6 to 12 days under these conditions. The residue from the operation consists of unreacted butadiene, some dimer and also small amounts of butene.

The preparation of butadiene from ethyl alcohol has already been discussed.[233g] The polymerization of this product, which is much purer than that obtained from petroleum cracking, is carried out on a commercial scale at 50-60°C. and 4 atmospheres, using metallic sodium as a catalyst.[234] The reaction takes place in both the gaseous and liquid phases, and is heterogeneous. At a given pressure, the rate is the same in both phases. After an initial period of acceleration, the speed slows down to a constant rate, due perhaps to the formation of primary sodium compounds. Polymerization is thought to proceed by the successive addition of mono-

[234] M. A. Lur'e and V. A. Ignatyuk, *loc. cit.*

meric molecules to these sodium compounds.[235] Mixed catalysts of sodium and iron oxide and sodium and magnesium oxide have also been investigated.[236]

Vulcanization of the polymerized product with sulphur is said to be much smoother than with the natural rubber. The technical treatment is the same. The properties of the synthetic product are reported as being satisfactory enough to serve as a substitute for rubber in many cases,[237] in fact, the claim is made that it is even stronger than the ordinary rubber.[238] The material is being used for tires,[239] rubber soles and heels, ebonite goods, raincoat cloth,[240] gasoline hose and tire tubes.[241]

OTHER USES OF POLYMERIZATION PRODUCTS

Many proposals have been made to utilize the numerous products of polymerization reactions besides those previously mentioned. Waste gases may be converted into illuminating gas by subjecting them to cracking at above 500°C., to enrich the olefin content.[242] The higher polymers of isobutene are recommended in making safety glass, plywood, adhesive plaster,[243] flypaper,[244] greases, lubricating and insulating oils,[245] chewing gum, wax for sealing tree wounds, a decay preventative,[246] and cleansing compounds.[247]

Bodies resulting from the polymerization of diolefins may be added to lubricating oils to improve the viscosity of the latter.[248] Other suggested uses are as rubber substitutes,[249] vulcanizable products,[249a] insulators[249b] and coating compositions.[250] The low-boiling ends of refinery gasoline (boiling below 21°C.) may be treated catalytically to form isoparaffinic hydrocarbons which may be employed to increase the viscosity of oils.[251] Using metallic halides (such as aluminum chloride) as the catalyst, at 38°C. these low-boiling fractions (containing isobutene) are converted to solids of a molecular weight greater than 800. Similarly, at slightly lower temperatures (27°C.) the polymer has a molecular weight of 4000 to 10,000. About 0.5 to 5 per cent by weight of this substance is usually blended with the lubricating oil. Hydrocarbons of this nature have been stated to increase the viscosity index of an oil from 93 to 120. On the other hand, liquid polymers have also been recommended as diluents in order to increase the fluidity of various oils obtained from lignite tar oils.[252] Products with molecular weights of 800 to 2000 may be added to greases and solid lubricants.[253] High-pressure condensation of cracked gasoline results in a liquid polymer which is reported to be a plasticizer[254] or a softener[255] for rubber. Cracked petroleum distillates may be polymerized to give higher boiling hydrocarbons which may be incorporated into synthetic resins[256] or oxidized with air, sulphur or chlorine to form asphaltic[257] and insulating[258] materials.

Chapter 27

Some Important Reactions of Diolefins

Diolefins are hydrocarbons having two ethylene linkages in their molecular structure. Their empirical formula corresponds to C_nH_{2n-2}. For classification, diolefins may be divided into three types:

(1) The allenes, possessing the characteristic structure,

$$>C{=}C{=}C<$$

(2) The conjugated dienes (or butadiene type), with the structure,

$$>C{=}\overset{|}{C}{-}\overset{|}{C}{=}C<$$

(3) Other diolefins in which the double bonds are separated from one another by one or more CH_2 groups, among which may be specially mentioned the 1,4- and 1,5-dienes.

Of the three classes, the one emphasized in this chapter is the butadiene type which exhibits a high degree of reactivity and condensing power. The latter property is used to a great extent in the industrial separation of diolefins from the products of pyrolysis of petroleum hydrocarbons.[1]

It is significant to note the increasing number of important diolefin derivatives obtained from condensation reactions. For example, Horclois[2] prepared derivatives of cyclopentadiene from alkylated diethyl malonates. These were used as starting materials in the synthesis of many compounds which have application both as pharmaceuticals and in the perfume industry.

Interaction of conjugated diolefins with substances such as halogens, halogen acids and sulphur dioxide, reactions of 2-chlorobutadiene and some analytical procedures are included in this chapter. Most of the resultants, with the possible exception of chloroprene, may seem to be of academic interest since they have been applied industrially only to a limited extent. However, they should be considered as possible sources for future development of organic chemical synthesis.

PREPARATION OF DIOLEFINS

Conjugated diolefins, particularly butadiene and cyclopentadiene, are often found among the products of high-temperature pyrolysis of petroleum hydrocarbons.[3] Another source is from the thermal decomposition of alcohols. For example, by the passage of ethyl alcohol vapor over a mixed catalyst, Lebedev[4] obtained a 20 to 25 per cent yield of butadiene. The importance of temperature and contact time in this process has been investigated by Volzhinskii, Kogan and Neimark.[5] In general, their results indicate that the stability of the butadiene is decreased in the presence of the catalyst. For example, when a gas containing 11.14 per cent of butadiene was passed through a depth of 2 meters of catalyst at the rate of 14.5 cc. per second at 500°C., the proportion of diolefin was reduced to 7.51 per cent.

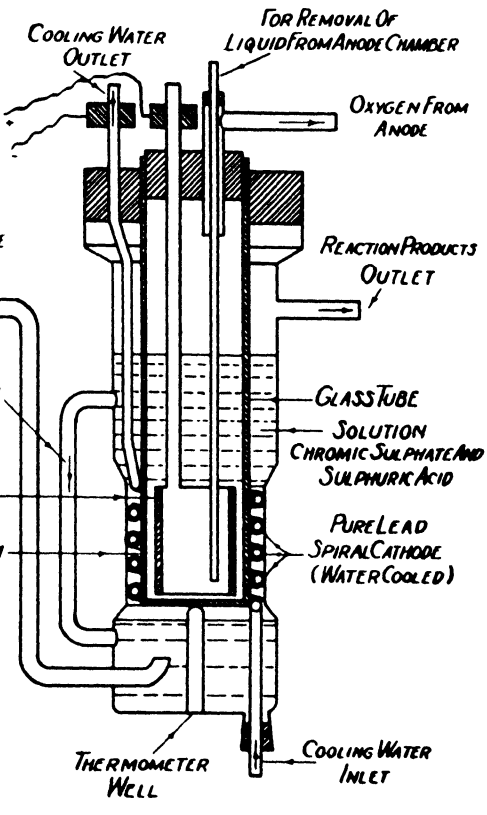

FIG. 151.—Sketch of Apparatus for Production of Butadiene. (P. Baumann and H. Tanneberger)

Diacetylene has been suggested by Baumann and Tanneberger[6] as a source of butadiene and they recommend the following procedure (See Fig. 151). In the reaction vessel is placed an aqueous solution which has the approximate composition: 11.6 per cent chromic sulphate, 5 per cent hydrogen sulphate and 83.4 per cent water. This solution is reduced electrolytically (using a cathode of pure lead), at a potential of about 5 volts and a current density of about 2.5 amperes per square decimeter of electrode surface. While this operation is being carried out at room temperature, or slightly above it, gaseous diacetylene (or a gaseous mixture

[5] I. A. Volzhinskii, G. M. Kogan and O. M. Neimark, *Sintet. Kauchuk*, 1936 (1), 4; *Chem. Abs.*, 1936, 30, 4147.

[6] P. Baumann and H. Tanneberger, U. S. P. 1,955,046, Apr. 17, 1934, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1934, 28, 3744.

of essentially this substance) is slowly passed through the liquid. The exit gases are reported to contain a large percentage (60 per cent or more) of butadiene.

Preparation of butadiene has been effected by using *n*-butyl chloride as a raw material. The procedure involved, as described by Muskat,[7] consists in chlorinating 1-chlorobutane, the temperature initially being 77°C. but rising to about 115°C. at the end of the operation. A mixture of dichlorides thus formed and boiling between 77° and 160°C. was separated (by distillation) into six fractions. Each fraction was separately distilled and the vapors passed in a steel tube heated to about 700-730°C. and containing coarse soda lime. After this treatment, the vapors traveled in succession through cooling vessels to remove water, unreacted dichlorobutane and tarry and resinous products. The nearly pure butadiene formed in this manner was collected as the tetrabromide made by bubbling the diolefin through chloroform containing bromine. In Table 145, the yields from each fraction are given.

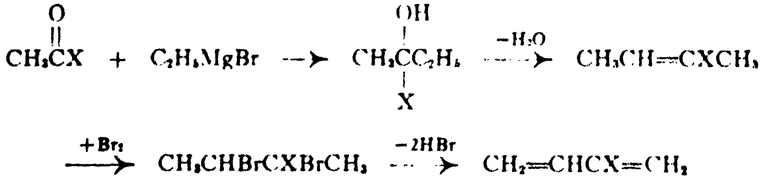
TABLE 145.—*Yields of Butadiene from Pyrolysis of Dichlorobutanes.*

Fraction Number	Boiling Range in °C.	Per cent Yield of Butadiene
1.	75-110	6.9
2.	110-120	18.8
3.	120-130	24.8
4.	130-140	29.6
5.	140-150	23.6
6.	150-165	25.6

In some instances homologues of this 1,3-diolefin may be obtained from derivatives of pinacone. For example, Backer and Strating[8] prepared 1,2,3,4-tetramethyl-1,3-butadiene in a 75 per cent yield by treating methylethylpinacone with hot 20 per cent sulphuric acid. This is represented as

$$\underset{\textit{methylethylpinacone}}{CH_3CH_2C(CH_3)(OH)C(CH_3)(OH)CH_2CH_3} \xrightarrow{-2H_2O} \underset{\textit{1,2,3,4-tetramethyl-1,3-butadiene}}{CH_3CH{=}C(CH_3)C(CH_3){=}CHCH_3}$$

Similarly, diethylpinacone, in the presence of alum at 140°C., was dehydrated to 1,4-dimethyl-2,3-diethyl-1,3-butadiene (b.p., 158-163°C.). The reactions by which two other compounds, 2-*ter*-butyl-1,3-butadiene (b.p., 104-106°C.) and 2-phenyl-1,3-butadiene (b.p. 58-59°C. at 9 mm.) were obtained, were also carried out by these workers. In both instances the starting material (a ketone) was treated with ethyl magnesium bromide and the resulting product was subsequently distilled in the presence of sulphuric acid. Bromination followed by another distillation under 25 millimeters pressure yielded the corresponding conjugated diene. This series of transformations is indicated below for the two examples mentioned. The symbol *X* represents either the *ter*-butyl or phenyl group.



$$CH_3\overset{\overset{O}{\|}}{C}X + C_2H_5MgBr \longrightarrow CH_3\overset{\overset{OH}{|}}{\underset{\underset{X}{|}}{C}}C_2H_5 \xrightarrow{-H_2O} CH_3CH{=}CXCH_3$$

$$\xrightarrow{+Br_2} CH_3CHBrCXBrCH_3 \xrightarrow{-2HBr} CH_2{=}CHCX{=}CH_2$$

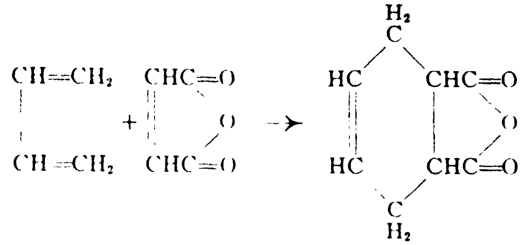
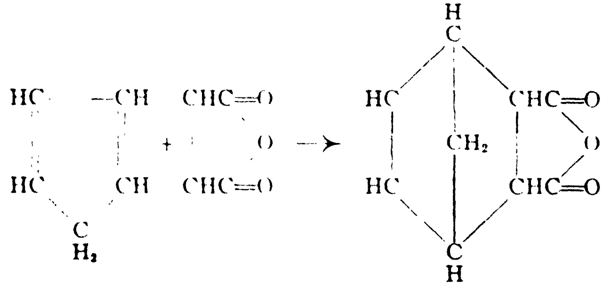
A small yield of 2,3-di-*ter*-butyl-1,3-butadiene was also secured by dehydrating 3-hydroxy-3,4-di-*ter*-butyl-1-butene with hot oxalic acid.

Horclois[9] reported that cyclopentadiene is obtained in the form of crystalline dicyclopentadiene as a by-product from coke oven gases. The rate of recovery is about 15 to 20 kilograms per 1000 tons of coal. As previously mentioned, certain derivatives of this cyclic 1,3-diolefin are applicable in the pharmaceutical and perfumery industries.

The separation of conjugated diolefins from crude benzol, or other liquid hydrocarbons, by interaction with maleic anhydride is described by Krzikalla and Wolff.[10] It is pointed out that by adding the anhydride in small portions and separating the resulting product after each addition, isolation of individual diolefins may be effected.[11] For butadiene the reaction can be represented as



and for cyclopentadiene as



In some instances, particularly with the latter diolefin and its homologues, *p*-quinones may be substituted for maleic anhydride.[12]

Reaction with quinones may be regulated so as to secure a separation of the diolefins. For example, Stern and Hoess[12a] suggest treatment of 1000 parts of cracked petroleum distillate (boiling up to 150°C.) with 70 parts of α-naphthoquinone. The liquid mass is then subjected to distillation (under reduced pressure), and the addition product of methylcyclopentadiene and α-naphthoquinone is secured as a residue. Interaction of the liquid with another portion (15 parts) of the quinone, followed by distillation, furnished a mixture of methylcyclopentadiene and cyclopentadiene adducts. Furthermore, another treatment with α-naphthoquinone (25 parts) and distilling yielded a residue of the addition product with cyclopentadiene.

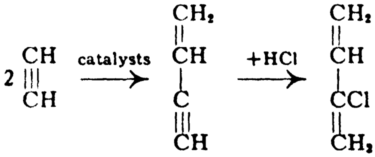
2-Chlorobutadiene. The industrial preparation of 2-chlorobutadiene is effected mainly by two reactions.[13] First, acetylene is polymerized in the presence of catalysts to form monovinylacetylene; and second, the latter hydrocarbon is treated with hydrogen chloride. These may be represented as follows:



$$2\,\begin{matrix}CH\\|||\\CH\end{matrix} \xrightarrow{\text{catalysts}} \begin{matrix}CH_2\\||\\CH\\|\\C\\|||\\CH\end{matrix} \xrightarrow{+HCl} \begin{matrix}CH_2\\||\\CH\\|\\CCl\\||\\CH_2\end{matrix}$$

acetylene *monovinylacetylene* *2-chloro-1,3-butadiene*
(chloroprene)

The presence of certain agents, especially cuprous chloride, causes an almost quantitative yield of this chlorolefin, or chloroprene, to be obtained in the second reaction. However, Nieuwland[14] pointed out that 2-chlorobutadiene is formed through an intermediate step. That is, a 1,4-addition of hydrogen chloride first takes place, and the resulting compound (chloromethylallene) then isomerizes to chloroprene under the influence of cuprous chloride.

$$CH_2{=}CH{-}C{\equiv}CH + HCl \rightarrow CH_2(Cl){-}CH{=}C{=}CH_2 \rightarrow CH_2{=}C(Cl){-}CH{=}CH_2$$

Another procedure comprises passage of vinylacetylene mixed with hydrogen chloride over activated charcoal.[14a] The latter may be coated with metallic chlorides, those of the heavier metals of Groups 2 and 4 of the Periodic System.

Using acetaldehyde and acetylene as starting materials, Carothers and Coffman[15] also synthesized 2-chlorobutadiene. In that method, a mixture of acetaldehyde and ether, at about —10°C., was treated for 8 hours with powdered sodamide and acetylene under superatmospheric pressure. The methylethinylcarbinol formed was purified and then dehydrated in the vapor phase by passage over basic aluminum sulphate at 240-260°C. Monovinylacetylene obtained in this way was freed of unchanged alcohol by fractional distillation. This was followed by cooling the hydrocarbon and reacting it with a thoroughly chilled mixture of hydrochloric acid, cuprous chloride and ammonium chloride in an autoclave. The product, after being held at 30°C. for 4 hours, yielded on steam distillation, from 75 to 92 per cent of chloroprene. The different steps in this operation may be represented by:

$$\underset{\textit{acetaldehyde}}{O{=}CHCH_3} + \underset{\textit{acetylene}}{HC{\equiv}CH} \longrightarrow \underset{\textit{methylethinylcarbinol}}{HC{\equiv}C{-}CHOHCH_3}$$

$$\xrightarrow{-H_2O} \underset{\textit{monovinylacetylene}}{HC{\equiv}C{-}CH{=}CH_2} \xrightarrow{+HCl} \underset{\textit{2-chloro-1,3-butadiene}}{CH_2{=}CClCH{=}CH_2}$$

Another method of preparation has been developed by Carothers.[16] 3,4-Dichloro-1-butene is caused to react with an amount of alkali (such as potassium hydroxide) which will remove half of the chlorine as hydrogen chloride, according to the following equation:

$$CH_2{=}CHCHClCH_2Cl \xrightarrow{+KOH} CH_2{=}CHCCl{=}CH_2$$

By fractional distillation, the product can be separated from any unreacted material. Carothers stated that 2-bromo-1,3-butadiene may be obtained in a similar manner.

Chloroprene is a colorless liquid which boils at 59.4°C. under atmospheric pressure and has a specific gravity of 0.9583 at 20°C. It undergoes polymerization to yield at least four distinct substances.[17] Of the latter, two types designated as α- and μ-polymers are the most important. The former is a soft, plastic body which is soluble in benzene, and has been marketed under the name of Duprene.[18] It may be separated from admixed polymers by precipitation with alcohol. The μ-variety resembles vulcanized rubber in physical properties, and is non-plastic and elastic.

In order to isolate the α-polyprene, Williams[19] has proposed two methods to effect separation of this polymer. First, when the polymerization mixture is of thick consistency (e.g., glycerol) or almost too thick to pour, a selective solvent is added. Such a compound dissolves the unreacted material and leaves free the soft rubbery mass. Further treatment with fresh solvent, followed by squeezing in a roll and heating to drive out last traces of the liquid are the subsequent steps used in this first process. Among the solvents that may be employed are methyl, ethyl, propyl, isopropyl and butyl alcohols, acetone, methyl ethyl ketone and diethyl ketone. The second method consists in distilling off the unchanged chloroprene under reduced pressure when polymerization has proceeded to the same extent as in the first procedure. Pressures recommended are from 6 cm. of mercury to atmospheric pressure and temperatures of from 25 to 70°C. A flexible, oil-resistant rubber composition of considerable tensile strength has been prepared from the benzene-soluble, alcohol-insoluble product of the complete or partial polymerization of chloroprene.[20]

Polymerization can be controlled by the use of added inhibitors such as a phenol, quinone, amine, nitro aryl compounds, ethyl selenide, iodine, bromine, certain sulphur-bearing organic compounds,[21] sulphur or thiuram disulphide.[22] The polymers are said to be more plastic at atmospheric temperatures when incorporated with 4 to 10 per cent of a ketone, for example, camphor, acetophenone, benzophenone or fenchone.[22a] Co-polymerization of chloroprene may be effected in the presence of diolefins such as 2,3-dimethylbutadiene,[22b] vinyl compounds,[23] e.g., ethers, esters, or carbinol derivatives, or α,β-unsaturated aldehydes, ketones, acids, esters, anhydrides or nitriles.[23a] Carothers[23b] advocates chlorination of polymeric 2-chlorobutadiene to secure rubber-like materials exhibiting flexibility even after long periods of storage or subjection to low temperatures. One method of treatment comprises dissolving the polymerized chlorohydrocarbon (30 parts) in chloroform (250 parts) and conducting a rapid stream of chlorine for 1.5 hours into the solution maintained at a temperature of 45°C. and out of contact with sunlight. Afterwards the liquid mass is kept at 20°C. for 16 hours. The solvent may then be removed by evaporation or the solid product precipitated by the addition of alcohol.

[18] Duprene is also known as Neoprene (see *Ind. Eng. Chem., News Ed.*, 1937, **15**, 43). The latter term has been suggested for use in a general sense, that is, it can designate the crude material or the products manufactured from it. In U.S.S.R., chloroprene synthetic rubber is referred to as Sovprene. Consult A. L. Klebanskii, L. G. Tzyurikh and I. M. Dolgopol'skii, *Bull. acad. sci. U.R.S.S.*, **1935** (2), 189; *J. Halogen Derivatives of Conjugated Diolefins

Addition of Bromine. Observations on the addition of halogens to most conjugated dienes indicate that the 1,4 compound is formed in the greatest amount.[24] From a theoretical standpoint, Eyring, Sherman and Kimball[25] arrived at this conclusion in the case of the addition of bromine to butadiene, the equation for which is given as follows:

$$CH_2{=}CHCH{=}CH_2 + Br_2 \longrightarrow CH_2BrCH{=}CHCH_2Br$$

They also stated that the reaction would be catalyzed by the walls of the container. Heisig and Wilson[26] made a kinetic study of this reaction carried out in various-sized spheres on glass and paraffined surfaces. The velocity constants were calculated, assuming that the reaction was bimolecular and that the reactants were weakly absorbed, using the formula

$$k = \frac{x}{at\,(a - x)}$$

where a is the initial partial pressure of bromine and butadiene (equal in this reaction) and x is the decrease in the pressure at the time t.

These investigators observed that the rate of reaction increased, in general, until a sufficient quantity of the product (1,4-dibromobutene) formed to saturate the gases with its vapor and also coat the walls of the spheres with a unimolecular layer. After that time the rate became constant. This phenomenon was not so apparent in large containers as in small ones. Some typical data obtained after the reacting gases were saturated with the dibromobutene are given in Table 146.

The increased reaction velocity with increase in surface is clearly shown in the case of the spherical containers packed with glass beads.

The product of the velocity constant k and the sphere diameter d was also found to be constant, and was considered as evidence for a surface reaction. Another conclusion drawn from the constancy of the product *kd* was "the reaction must occur on a surface of reaction product rather than the wall itself." Some values of *kd* are shown in Table 147. In each instance equimolecular volumes of butadiene and bromine were employed.

The bromination of cyclopentadiene has been shown to be incomplete when conducted in air, due to the absorption of oxygen.[27] The observation led Heisig and Davis[28] to study the effect of oxygen on the reaction between bromine and butadiene. They found that the rate of reaction increased with the decrease of oxygen present, and that the increase was especially noticeable when the partial pressure of the oxygen was well below 2 mm. This is illustrated by data in Table 148. In all instances the course of combination of gaseous olefin and halogen was measured by the decrease in pressure (in mm. of α-bromonaphthalene, the manometer fluid) within the reaction vessel.

TABLE 148.—***Reaction between Bromine and Butadiene with Various Concentrations of Oxygen.***

∞		28.7	29.6	25.3	27.0

On the basis of their data, the conclusion was made that transformation first took place mainly at the surface of the container. The sensitivity of the rate of reaction to oxygen suggests a chain mechanism with short chains begun at that surface.

Bromination of butadiene was employed by Tzyurikh and Rotenberg[29] in the synthesis of 1,4-dibromobutane. The resulting mixture of stereoisomeric 1,4-dibromo-2-butenes was converted to 1,4-diethoxy-2-butene by wetting with a little alcohol and gradually mixing with a calculated amount of sodium ethylate. The ether thus formed was hydrogenated at room temperature in alcohol using palladium and nickel catalysts, and yielded 1,4-diethoxybutane. The latter was heated in a sealed tube with concentrated hydrogen bromide at 130°C. for 3 hours to give 1,4-dibromobutane. This series of reactions is outlined in the following scheme.

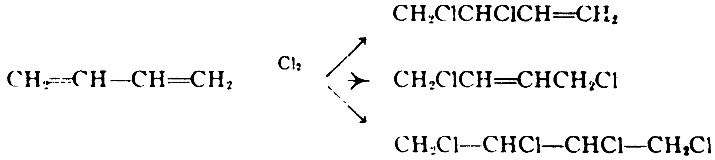
Addition of Chlorine. Interaction of chlorine and butadiene furnishes a mixture of 1,2- and 1,4-dichlorobutenes, of which the latter is formed in the greater proportion. At the same time some tetrachlorobutadiene (both *cis* and *trans* forms) is produced.[30] These reactions can be represented by:



In the preparation of these compounds, Muskat[31] suggests that the gaseous diolefin and halogen be passed simultaneously into a liquid medium (e.g., carbon disulphide) cooled by an ice-salt bath. The resulting mixture of chlorinated compounds may be separated afterwards by fractional distillation. He also points out that both 1,2- and 1,4-dichloro compounds polymerize when subjected to the action of alkaline (for example, sodium hydroxide, soda-lime, or ammonia) or acidic (such as sulphuric acid, zinc chloride or boron trifluoride) condensing agents. These polymers are brown, solid resins.

When 1,4-dichlorobutene-2, mixed with twice its weight of powdered potassium hydroxide, is heated to about 90°C., dechlorination occurs with the formation chloro-1-butadiene-1,3.

$$CH_2ClCH=CHCH_2Cl \longrightarrow CHCl=CH-CH=CH_2 + HCl$$

This is a colorless liquid boiling at 67-68°C., has a density of about 0.958 (at 20°C.) and a refractive index (n_D^{20}) of 1.470. On standing, it polymerizes spontaneously to a colorless resin.

According to Muskat, dechlorination (as described above) of the mixed dichlorobutenes furnishes chloro-1-butadiene-1,3, monovinylacetylene, an acetylenic hydrocarbon (of undetermined structure), and a resinous body (as a residue). The first three may be separated by fractional distillation, and each subjected to polymerization to give almost colorless resins. Co-polymerization of the two acetylene derivatives admixed with 1-chlorobutadiene may be effected also. The recommended mode of operation is application of pressure to the compounds in the presence of air and with exposure to light.

Chlorination of isoprene has been investigated by Jones and Williams.[32] These workers added a carbon tetrachloride solution of chlorine to a solution of isoprene in the same solvent over a period of 4 hours, the mixture being mechanically stirred and cooled by an ice-salt bath. The resulting composite was fractionated and the substances obtained are listed in Table 149.

Addition of Halogen Acids. As in the case of bromine, the presence of oxygen affects the addition of hydrogen bromide to butadiene. Kharasch, Margolis and Mayo[33] found that a yield of 70 to 90 per cent of 1-bromo-2-butene was obtained in air and also in the presence of added peroxides. But, in the absence of oxygen and in the presence of antioxidants, hydrogen bromide combines with butadiene to give 2-bromo-2-butene in 65 to 90 per cent yields. These workers suggested that 1-bromo-2-butene could have been formed either by direct 1,4 addition or by a rearrangement of the 2-bromo-2-butene under the influence of hydrogen bromide alone or with peroxides. Ganguly[33a] reports that interaction of hydrogen chloride and butadiene furnishes the two isomers $CH_3CHClCH{=}CH_2$ and $CH_3CH{=}CHCH_2Cl$. The third isomer, $CH_2ClCH_2CH{=}CH_2$, was not detected.

Combination of halogen acids and 1,3-dienes generally takes place in the 1,4 position. However, there are exceptions, as in the reaction just mentioned. In another example, negative group substitutions in butadiene (in the cases of 1-phenylbutadiene and 1-bromobutadiene) have been noted to result in a 3,4 addition of hydrogen bromide. Muskat and Huggins[34] showed that hydrogen chloride reacts with the geometric isomers of 1-phenylbutadiene to form the *cis-* and *trans-*1-phenyl-3-chloro-1-butene, which boil at 106°C. (at 5 mm.) and 103°C. (at 5 mm.), respectively. Their structures were determined by ozonization to be the result of absorption in the 3,4 positions. That these compounds were 3-chloro derivatives was shown by identifying the hydroxy derivative of the *cis* isomer and comparing the *trans* isomer with the hydrogen chloride addition product of *trans-*1-phenyl-3-hydroxy-1-butene.

The action of dry hydrogen chloride under pressures of about 10 atmospheres on butadiene compounds and their polymers results in a material which is spongy and asbestos-like in texture. The time of reaction is about 8 hours and can be decreased by using catalysts as, e.g., aluminum chloride. The product thus formed, after removal of excess hydrogen chloride, is relatively stable at 100°C. and may be used in the manufacture of transparent films.[35]

Substituted Derivatives. The preparation of 2,3-dichlorobutadiene has been described by Carothers and Berchet.[36] In that process, 1,2,3,4-tetrachlorobutane is treated with a 30 per cent methyl alcohol solution of potassium hydroxide or with solid sodium hydroxide at 10° to 18°C. The reaction in this instance is:

---

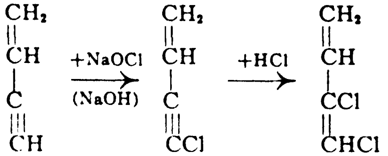
$$CH_2Cl{-}CHCl{-}CHCl{-}CH_2Cl \xrightarrow{+2KOH} CH_2{=}CCl{-}CCl{=}CH_2 + 2KCl + 2H_2O$$

The synthesis of 1,2-dichlorobutadiene has been reported,[37] and is briefly as follows: monovinylacetylene is shaken for 16 hours with aqueous sodium hypochlorite containing 15 per cent of sodium hydroxide. This is followed by treatment for 16 hours with fuming hydrochloric acid (acid of sp. gr. 1.19 in which about 50 per cent more hydrogen chloride has been dissolved), cuprous chloride and ammonium chloride. The two steps may be summarized as follows:

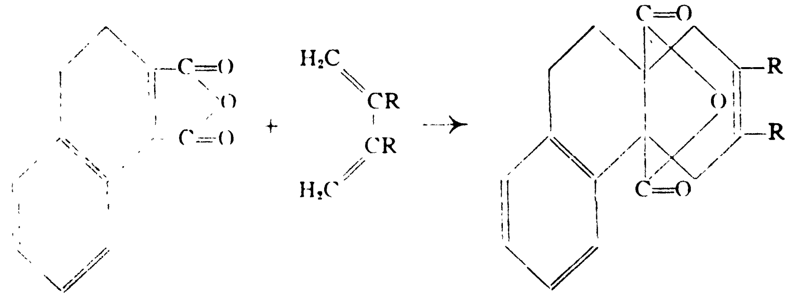


$$CH_2{=}CH{-}C{\equiv}CH \xrightarrow[(NaOH)]{+NaOCl} CH_2{=}CH{-}C{\equiv}CCl \xrightarrow{+HCl} CH_2{=}CH{-}CCl{=}CHCl$$

The product has a boiling point of 60-65°C. at 105 mm., and can be polymerized spontaneously to a rubbery substance which may be vulcanized to an ebonite-like material.

CONDENSATION REACTIONS OF CONJUGATED DIOLEFINS

Butadiene enters into direct combination with many aromatic compounds. Fieser and Hershberg[38] state that the following reaction is of general application to synthesis:



where *R* is an alkyl group or hydrogen. For example, these investigators prepared 1,4,9,10,11,12-hexahydrophenanthrene-11,12-dicarboxylic acid anhydride (b.p., 160-170°C.) in a 63 per cent yield by heating butadiene with 3,4-dihydronaphthalene-1,2-dicarboxylic acid anhydride for 85 hours at 100°C. Using 2,3-dimethyl-1,3-butadiene, the compound 2,3-dimethyl-1,4,9,10,11,12-hexahydrophenanthrene-11,12-dicarboxylic acid anhydride was also obtained. Other compounds prepared were 2,3-dimethyl-1,4,11,12,13,14-hexahydrochrysene-13,14-dicarboxylic acid anhydride

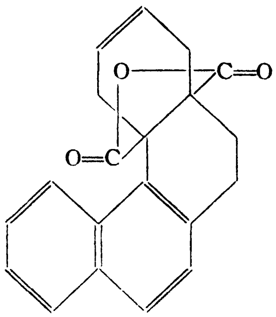
and 5,6-benz-1,4,9,10,11,12-hexahydrophenanthrene-11,12-dicarboxylic acid anhydride

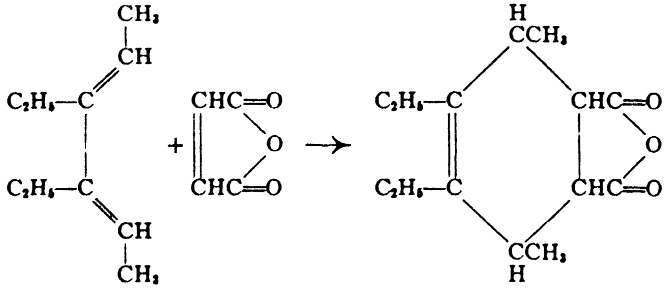


The condensations mentioned above involve a system of conjugated double bonds, found in the butadiene type of diolefins, reacting with the grouping

$$-\overset{|}{C}=\overset{|}{C}-\overset{|}{C}=O$$

Diels and Alder[39] include in this class of reactants quinones, maleic acid, maleic anhydride, itaconic anhydride and citraconic anhydride which easily form condensation products with conjugated diolefins as butadiene, cyclopentadiene and phellandrene. Among the many addition compounds thus prepared were terpenes, sesquiterpenes, alkaloids, camphors and hydrogenated cyclic compounds.

A further example is the interaction between maleic anhydride and 1,4-dimethyl 2,3-diethylbutadiene (b.p., 158-163°C.) to form 1,4-dimethyl-2,3-diethyl-1,4,5,6-tetrahydro-phthalic anhydride.[40]

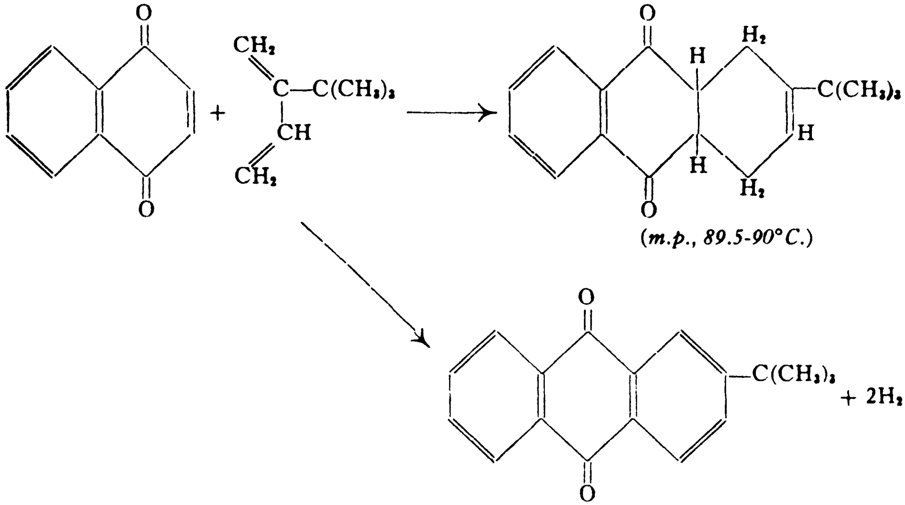


---

[39] O. Diels and K. Alder. U. S. P. 1.944,731, Jan. 23, 1934, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1934, **28**, 2016. See also Carleton Ellis, "The Chemistry of Synthetic Resins," Reinhold Publishing Corp., New York, 1935, Chapter 40 for a discussion of the "Diene Synthesis."

[40] H. J. Backer and J. Strating, *Rec. trav. chim.*, 1934, **53**, 525; 1935, **54**, 170; *Brit. Chem. Abs.* **A**, 1934, 662; 1935, 497; *Chem. Abs.*, 1934, **28**, 4697; 1935, **29**, 2959.

The use of quinones in place of acid anhydrides is illustrated by the union of 2-*ter*-butylbutadiene (b.p., 104-106°C.) and naphthaquinone to yield 2-*ter*-butylanthraquinone and 2-*ter*-butyl-1,4,13,14-tetrahydroanthraquinone.[41] This may be expressed as follows:



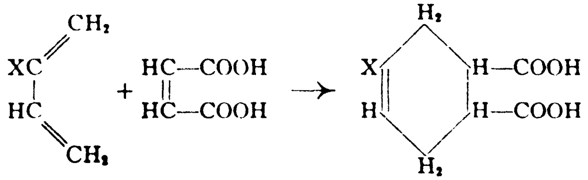
(*m.p., 89.5-90°C.*)

(*m.p., 104-105°C.*)

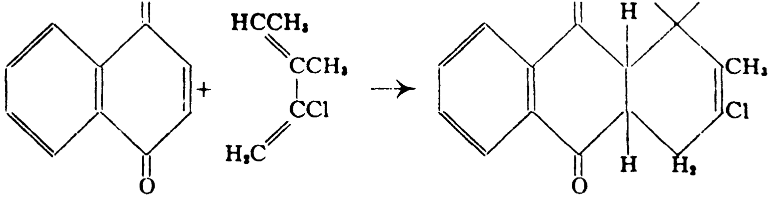
According to Carothers and Collins,[42] cyclic derivatives may be prepared by condensing 2-substituted 1,3-dienes with compounds containing a system of double bonds, many of which have the afore-mentioned structure

$-\overset{|}{C}=\overset{|}{C}-\overset{|}{C}=O$

The following are two examples of this type of reaction.



X = Cl or Br



1,4-naphthaquinone *3-chloro-1,2-dimethylbutadiene* *3-chloro-1,2-dimethyl-1,4,4a,9a-tetrahydroanthraquinone* (m.p., 107°C.)

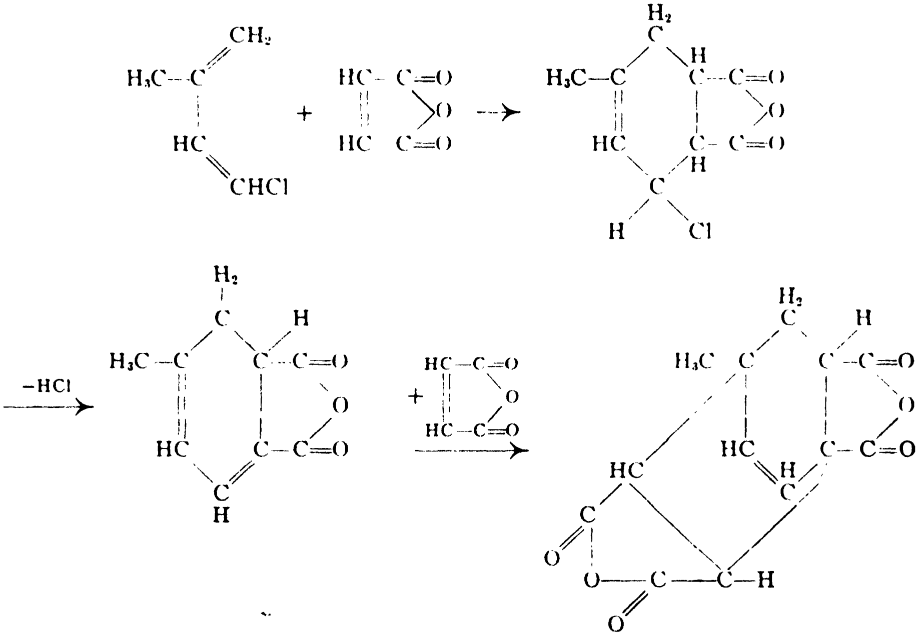
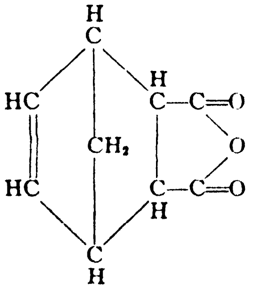
[42] W. H. Carothers and A. Collins, U. S. P. 1,967,862, July 24, 1934, to E. I. du Pont de Nemours & Co., *Chem. Abs.*, 1934, 28, 5994; *Brit. Chem. Abs.* B, 1935, 621.

These workers obtained intermediates of dyes, perfumes and medicinal compounds by analogous procedures.

An unusual condensation of 2-methyl-4-chlorobutadiene with maleic anhydride was observed by Favorskii and Favorskaya,[43] in which the transformation was accompanied by a vigorous evolution of hydrogen chloride gas. They believed that the following represents the course of the reaction finally resulting in a tetracarboxylic acid (or its anhydride).



It is interesting to note that methylene tetrahydrophthalic acid anhydride has



(m.p., 162° C.)

been isolated from the products obtained by treatment of crude benzol (from coke ovens and gas plants) with maleic anhydride.[44]

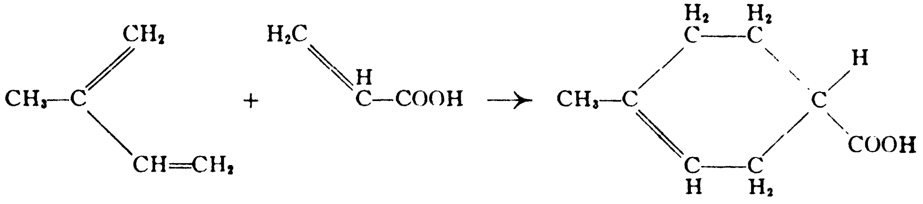
Isoprene has been found to condense with acrolein or acrylic acid, both of which contain a system of conjugated double bonds.[45] For instance, acrylic acid reacts with isoprene at about 110°C. in an autoclave to give 4-methyl-1,2,3,6-tetrahydrobenzoic acid. The reaction may be represented as follows:

---

[43] A. Favorskii and T. Favorskaya, *Compt. rend.*, 1935, **200**, 839; *Chem. Abs.*, 1935, **29**, 3651; *Brit. Chem. Abs.* **A**, 1935, 605.

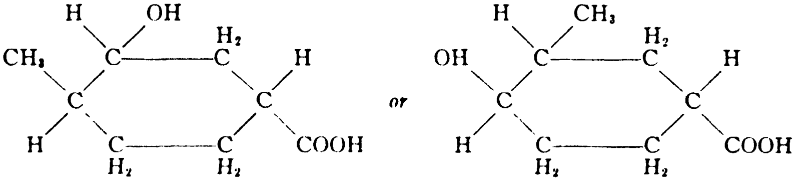
[44] British P. 352,164, 1931 and 438,810, 1935, to I. G. Farbenind. A.-G.; *Brit. Chem. Abs.*, **B**, 1931, 962; 1936, 137; *Chem. Abs.*, 1932, **26**, 3261; 1936, **30**, 3220; *J. Inst. Pet. Tech.*, 1936, **22**, 55A.

[45] E. Lehmann and W. Paasche, *Ber.*, 1935, **68**, 1068; *Brit. Chem. Abs.* **A**, 1935, 974; *Chem. Abs.*, 1935, **29**, 5428.



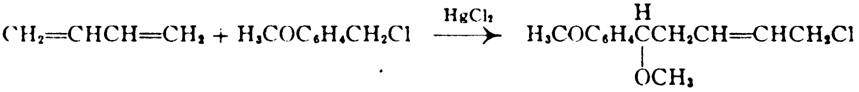
(*m.p., 135-140°C.*)

This 1,4 addition is also accompanied by the formation of a small amount of 3(4)-methyl-4(3)-hydroxy-cyclohexane-1-carboxylic acid:



(*m.p., 156°C.*)

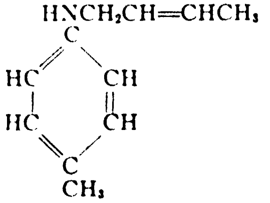
Other types of condensations of conjugated diolefins have been studied by Straus and Thiel.[46] They prepared 1-anisyl-1-methoxy-5-chloro-3-pentene (b.p., 104°C. at 0.1 mm.) by treating butadiene (in the presence of mercuric chloride) with *p*-methoxy-benzylchloride.



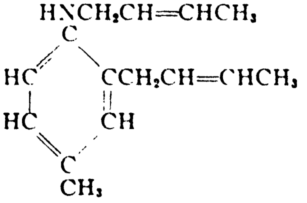
$$CH_2{=}CHCH{=}CH_2 + H_3COC_6H_4CH_2Cl \xrightarrow{HgCl_2} H_3COC_6H_4\overset{H}{C}(OCH_3)CH_2CH{=}CHCH_2Cl$$

In addition, these workers also obtained such compounds as 1-phenyl-1-methoxy-5-chloro-3-pentene (b.p., 126-127°C. at 12 mm.) and 1-methoxy-5-chloro-3-pentene (b.p., 56°C. at 10 mm.).

Interactions of butadiene with aryl amines were reported by Hickinbottom,[47] who heated aniline solutions of butadiene (8 to 12 per cent) in the presence of aniline hydrochloride or hydrobromide in a sealed tube at 220 to 260°C. for 4 to 25 hours. From the resulting mixture, 1-*p*-aminophenyl butene-2 (b.p., 135-136°C. at 24 mm.), 1-phenylamino butene-2 (b.p., 132-134°C. at 34 mm.) and 2,3-dimethyl-indole (m.p., 105-106°C.) were separated. In a similar manner, *p*-toluidine and butadiene furnished 2,3,5-trimethylindole (m.p., 120-121°C.) and the following compounds:



(*b.p., 135°C. at 33 mm.*)



(*b.p., 185°C. at 30 mm.*)

---

[46] F. Straus and W. Thiel, *Ann.*, 1936, **525**, 151; *Brit. Chem. Abs.* **A**, 1936, 1375; *Chem. Abs.*, 1937, **31**, 363.

[47] W. J. Hickinbottom, *J.C.S.*, **1934**, 1981; *Chem. Abs.*, 1935, **29**, 1399; *Brit. Chem. Abs.* **A**, 1935, 205.

The autopolymerization of butadiene has been observed by Khokhlovkin[48] to be complete in 515 days, if light is present. It was found that 427 days were required to produce enough polymer to catalyze the reaction to a more appreciable rate than during this period. That is, it was noted that about 85 per cent of the polymers were formed in the final relatively short period of 88 days.

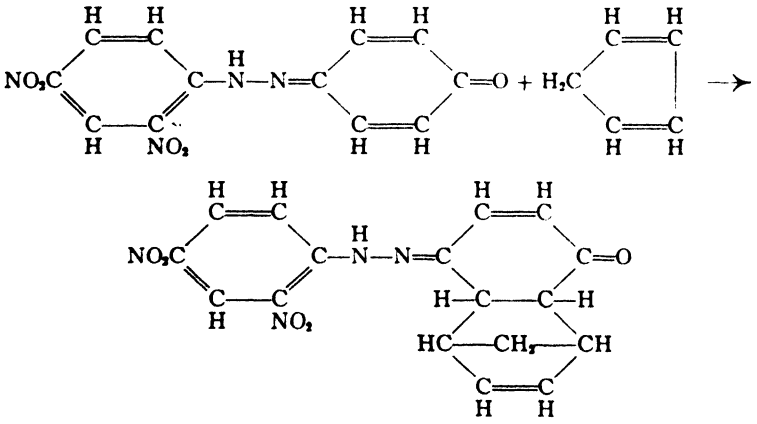
Days	Per Cent of Polymer Formed
427	14.8
486	62.5
515	100.0

The speed of autopolymerization in the absence of light was found to decrease considerably.

CYCLODIENE CONDENSATION REACTIONS

Cyclopentadiene[49] has been found to add to certain hydroxyazo compounds. Lauer and Miller[50] provided definite evidence that the latter show a quinoid character by means of such condensations.[51]

Addition of 2,4-dinitro-benzeneazophenol to cyclopentadiene was carried out in various concentrations of sodium acetate and chloroacetic acid in glacial acetic acid. After being refluxed on steam baths for about 3 hours (5 hours in one case) these mixtures were then cooled at 10-15°C. for 10 days in order to crystallize the crude product. Purification was effected by recrystallization from either acetic acid, ethyl acetate, pyridine or acetic anhydride. The reaction may be represented as:



In Table 150, the results of carrying out this reaction in the various media are shown. The yields of addition product show an increase with increased chloroacetic acid content of the glacial acetic acid.

	.860	48.6
	.803	45.4
	.781	44.1

[a] This was glacial acetic acid to which was added sodium acetate, mono- or dichloroacetic acid.

However, Lauer and Miller state that not all *p*-hydroxyazo compounds combine with cyclopentadiene. He lists a number of these which are shown in Table 151. The letters *a, b, c,* etc., represent points at which substitution occurred while under each letter is placed the substituting group. For example, compound (1) was a dinitrodibromohydroxyazo benzene. Other compounds condensing with cyclopentadiene investigated by these experimenters include 2',4'-dinitro-4-hydroxy-2-bromoazobenzene and quinoneazine,

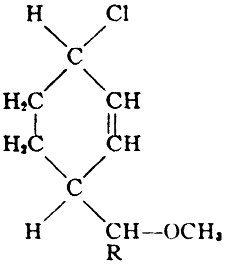
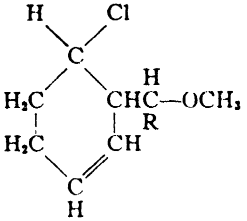
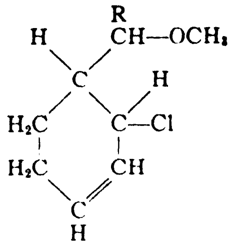
Cyclohexadiene condensation reactions have been studied by Straus and Thiel.[52] These workers reported additions (in the presence of mercuric chloride) with α-methoxy-benzylchloride to form ω-methoxy-benzyl-chloro-cyclohexene (b.p., 112°C. at 0.1 mm.), and monochlorodimethyl ether to form ω-methoxy-methyl-chlorocyclohexene (b.p., 81°C. at 10 mm.) These two compounds were believed to be a mixture of 1,2 and 1,4 addition products as shown by the following formulas, in which R may be either a phenyl group or a hydrogen atom.

---

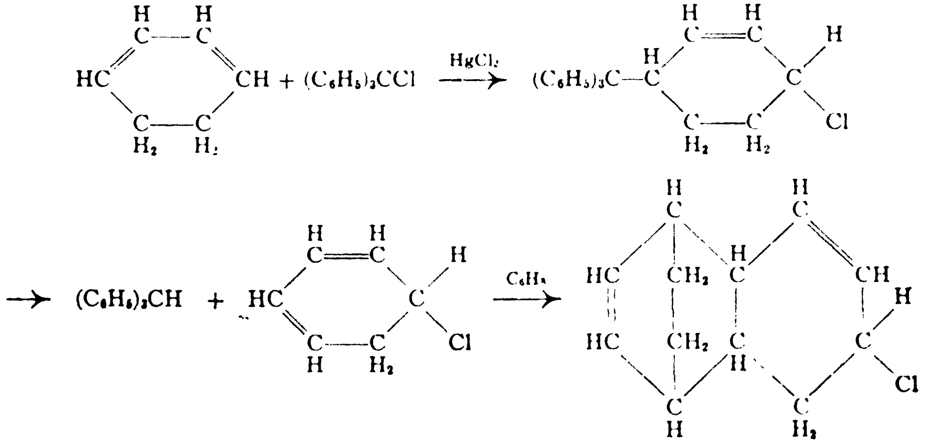
[52] F. Straus and W. Thiel, *Ann.*, 1936, 525, 151; *Brit. Chem. Abs.* A, 1936, 1375; *Chem. Abs.*, 1937, 31, 363.







The anisyl derivative of the last named compound was also prepared. An interesting reaction took place between cyclohexadiene and triphenyl-chloro-methane. The first step seemed to be a direct addition followed by the splitting off of triphenyl methane, which was isolated. The chloro-derivative formed appeared to unite with another molecule of cyclopentadiene to produce a monochloro-1,4-endoethylene-1,4,5,6,9,10-hexahydronaphthalene. One of the possible courses of this series of reactions is illustrated below:



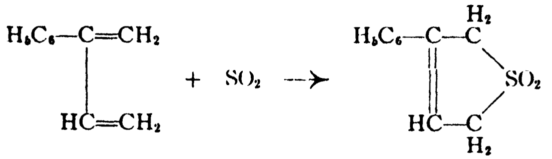
Butadiene Sulphones

Sulphur dioxide readily combines with butadiene homologues to form sulphones.[53] In the experiments of Backer and Strating,[54] the reaction between 2,3-dimethyl-1,3-butadiene and an ethyl ether solution of sulphur dioxide at 100°C. resulted in a 60 per cent yield of the sulphone, 3,4-dimethyl-1-thia-3-cyclopentene 1,1-dioxide (m.p., 135°C.). In the same manner 1,2,3,4-tetramethyl-1,3-butadiene gave 2,3,4,5-tetramethyl-1-thia-3-cyclopentene 1,1-dioxide (m.p., 58-59°C.). Bromination of the first compound in carbon tetrachloride followed by treatment with hot normal sodium hydroxide solution yielded the corresponding *trans*-diol derivative. On the other hand, the *cis*-diol was formed by omitting the bromination step. These workers also prepared the sulphones of other butadiene homologues. For example, 2-phenylbutadiene combined with sulphur dioxide in ethyl ether yielded 3-phenyl-1-thia-3-cyclopentene 1,1-dioxide. In equation form,

---

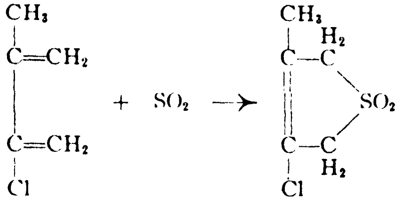
[53] For previous work see Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co. Inc., New York, 1934, 654.

[54] H. J. Backer and J. Strating, *Rec. trav. chim.*, 1934, 53, 525; 1935, 54, 170; *Brit. Chem. Abs.* A, 1934, 662; 1935, 497; *Chem. Abs.*, 1934, 28, 4697; 1935, 29, 2959.



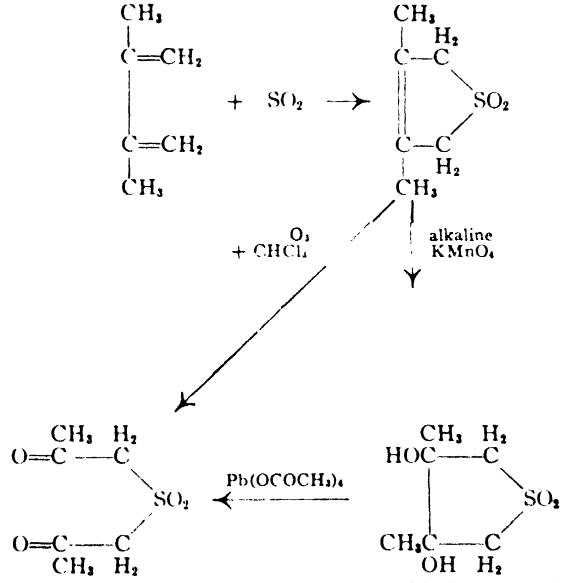
(*b.p., 58-59°C. at 9 mm.*) (*m.p., 132.5-133.5°C.*)

Also 2-chloro-3-methyl-butadiene similarly treated resulted in 4-chloro-3-methyl-1-thia-3-cyclopentene 1,1-dioxide. This is represented as follows:



(*m.p., 120-120.5°C.*)

Zuydewijn and Böeseken[55] obtained 2,3-dimethyl-3-thia-cyclopentene 1,1-dioxide from 2,3-dimethyl-1,3-butadiene and sulphur dioxide. Oxidation of the product by alkaline potassium permanganate yielded the *trans*-diol, which, in the presence of lead tetraacetate, was further oxidized to diacetonyl sulphone. The structure of the latter compound was confirmed by oxidation of the sulphone, in chloroform solution, with ozone. The various steps are indicated in the following manner:



diacetonyl sulphone (*m.p., 43°C.*)

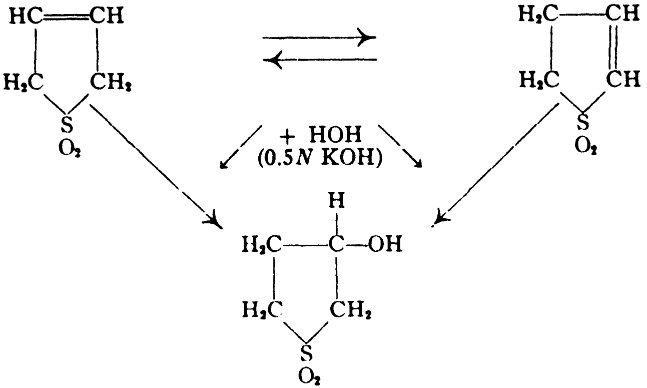
trans-3,4-dihydroxy-3,4-dimethyl-1-thiacyclopentane 1,1-dioxide (56)

According to Böeseken and Zuydewijn,[57] butadiene sulphone, in 0.5*N* potassium hydroxide, exists in two isomeric forms. Either of these are hydrated, in alkaline solution to give a hygroscopic hydroxysulphone.

---

[55] E. van Zuydewijn and J. Boeseken, *Rec. trav. chim.*, 1934, **53**, 673; *Chem. Abs.*, 1934, **28**, 4697; *Brit. Chem. Abs.* **A**, 1934, 900.

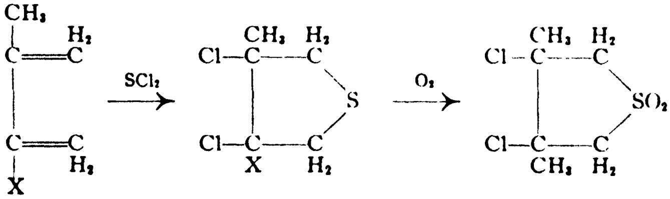
[56] For nomenclature of organic compounds see A. M. Patterson, *J.A.C.S.*, 1933, **55**, 3905; *Chem. Abs.*, 1933, **27**, 5304.



(m.p., 35°C.)

Furthermore, this alcohol is not converted (in potassium hydroxide solution) into either form of butadiene sulphone by the action of ultraviolet light. These experimenters therefore concluded that the tautomeric conversion of the above sulphone does not take place by the addition and separation of water, as was suggested by Backer and Strating.[58]

Sulphones may be prepared also by the interaction of conjugated diolefins with sulphur chloride followed by oxidation of the resulting product. Thus, Backer and Strating[59] reacted sulphur chloride with 2,3-dimethylbutadiene in an ice-salt bath for several hours and procured 3,4-dichloro-3,4-dimethyl-thiacyclopentane. This compound, when dissolved in acetic acid and treated with oxygen, was converted into the sulphone, 3,4-dichloro-3,4-dimethyl-1-thiacyclopentene 1,1-dioxide [m.p., 265°C. (decomposes)]. In a similar manner, isoprene furnished 3,4-dichloro-3-methyl-thiacyclopentene 1,1-dioxide (m.p., 144.5-145.5° C.). These reactions may be represented as follows, where X represents either hydrogen or a methyl group.



Miscellaneous Reactions of Diolefins

Allene reacts with nitrogen trioxide in cold ether, according to Dem'yanov and Ivanov,[60] to form a crystalline nitrosite, $C_3H_4N_2O_3$ (m.p., 89°C., decomposition),

---

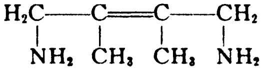
[57] J. Böeseken and E. van Zuydewijn, *Proc. Acad. Sci. Amsterdam*, 1936, **39**, 31; *Chem. Abs.*, 1936, **30**, 3403; *Brit. Chem. Abs.* **A**, 1936, 589.

[58] H. J. Backer and J. Strating, *Rec. trav. chim.*, 1935, **54**, 618; *Chem. Abs.*, 1936, **30**, 3403; *Brit. Chem. Abs.* **A**, 1935, 1105.

[59] H. J. Backer and J. Strating, *Rec. trav. chim.*, 1935, **54**, 52; *Brit. Chem. Abs.* **A**, 1935, 325; *Chem. Abs.*, 1935, **29**, 2504.

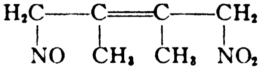
[60] N. Y. Dem'yanov and A. A. Ivanov, *Compt. rend. acad. sci. U.R.S.S.*, 1934, **1**, 318; *Chem. Abs.*, 1934, **28**, 4374; *Brit. Chem. Abs.* **A**, 1934, 508. See also Carleton Ellis, *loc. cit.*, 580, for reactions of nitrogen trioxide with olefins.

and a very unstable liquid. Purification of the nitrosite was effected by recrystallizing from hot acetic acid. These investigators also isolated the nitrosite $C_6H_{10}N_2O_3$ (m.p., 104-105°C.) and a liquid product from the reaction between nitrogen trioxide and dimethylbutadiene. The liquid was converted to a diamine (by tin and hydrochloric acid) which affected polarized light. The hydrogen chloride salt when heated in a test tube gave evidence of the pyrrole reaction. With these reactions as a basis, the structure of the amine was suggested as



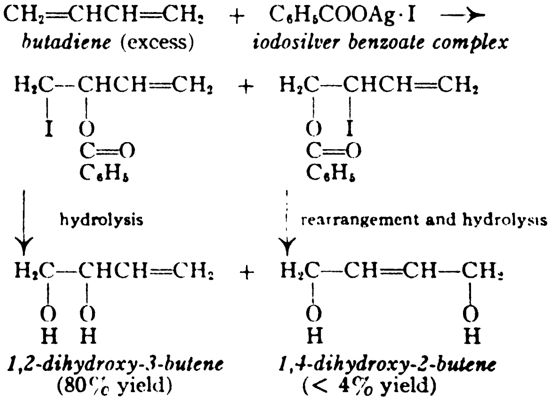
$$\begin{array}{cccc} H_2C & -\!\!-C & =\!\!=C & -\!\!-CH_2 \\ | & | & | & | \\ NH_2 & CH_3 & CH_3 & NH_2 \end{array}$$

and for the original liquid



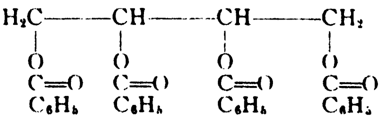
$$\begin{array}{cccc} H_2C & -\!\!-C & =\!\!=C & -\!\!-CH_2 \\ | & | & | & | \\ NO & CH_3 & CH_3 & NO_2 \end{array}$$

Although the example of a 1,4-addition just given is of the general reaction type, there are exceptions. For example, the action of iodosilver benzoate[61] on an excess of butadiene was found to result in mainly the 1,2 union. The determination was made by hydrolyzing the resulting mixture and separating out 1,2-dihydroxy-3-butene in an 80 per cent yield and 1,4-dihydroxy-2-butene in less than 4 per cent yield. Therefore it was concluded by Prévost and Lutz[62] that the complex added mainly to the 1 and 2 positions rather than the 1 and 4. That the latter addition product was not obtained as a major intermediate in the experiments was explained by suggesting that the iodine would probably migrate to the 4 position, as bromine does. The reactions are represented below:



$CH_2{=}CHCH{=}CH_2$ + $C_6H_5COOAg{\cdot}I$
butadiene (excess)
iodosilver benzoate complex
hydrolysis
rearrangement and hydrolysis
1,2-dihydroxy-3-butene
(80% yield)
1,4-dihydroxy-2-butene
(< 4% yield)

Using an excess of the silver complex, a 60 per cent yield of mesotetrabenzoylerythritol (m.p., 187°C.) was secured. This may be represented by the following:



$$\begin{array}{cccc} H_2C & -\!\!-CH & -\!\!-CH & -\!\!-CH_2 \\ | & | & | & | \\ O & O & O & O \\ C{=}O & C{=}O & C{=}O & C{=}O \\ C_6H_5 & C_6H_5 & C_6H_5 & C_6H_5 \end{array}$$

meso-tetrabenzoylerythritol

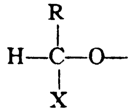
---

[61] According to H. Wieland. F. G. Fischer (*Ann.*, 1925, 446, 49; *Chem. Abs.*, 1926, 20, 408), silver benzoate, $(C_6H_5)COOAg$, in ether or benzene suspension, absorbs 1 equivalent of iodine at room temperature to form iodosilver benzoate. This complex decomposes in water to give benzoic acid, silver iodide and silver iodate.

[62] C. Prévost and R. Lutz, *Compt. rend.*, 1934, 198, 2264; *Chem. Abs.*, 1934, 28, 6105; *Brit. Chem. Abs.* A, 1934, 989.

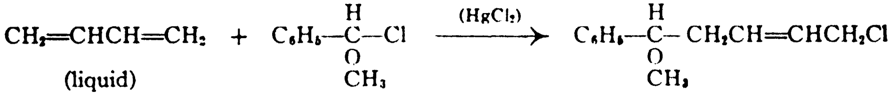
According to Carpenter,[63] dicarboxylic acids can be produced by the combination of diolefins and formic acid. Limits of conditions recommended are pressures of 25 to 900 atmospheres and temperatures of 100-500°C.

Halogenated ethers have been obtained by the combination of butadiene and alkoxyalkyl halides of the general formula



$$H-\overset{\displaystyle R}{\underset{\displaystyle X}{C}}-O-R^1$$

where R is hydrogen, alkyl, aryl or aralkyl group, R^1 is alkyl, aryl or aralkyl group, and X is a halogen atom.[64] An example of this type of reaction is that of butadiene with methoxybenzyl chloride, employing mercuric chloride as a catalyst.



$$\underset{\text{(liquid)}}{CH_2{=}CHCH{=}CH_2} + C_6H_5-\overset{\displaystyle H}{\underset{\displaystyle \overset{O}{CH_3}}{C}}-Cl \xrightarrow{(HgCl_2)} C_6H_5-\overset{\displaystyle H}{\underset{\displaystyle \overset{O}{CH_3}}{C}}-CH_2CH{=}CHCH_2Cl$$

1-phenyl-1-methoxy-5-chloro-3-pentene
(b.p., 93°C./0.01 mm.)

Among the other compounds[65] that were produced in a similar manner are 1-methoxy-5-chloro-3-pentene (b.p., 118°C.), 1-phenyl-1-methoxy-5-bromo-3-pentene (b.p., 92°C. at 0.05 mm.) and 1-methoxybenzyl-2-chlorocyclohexane (b.p., 94.5°C. at 0.01 mm.)

Passage of the diolefin into an ether solution of thiocyanogen is said to result in an 80 per cent yield of the dithiocyano derivative.[65a] Addition in this instance takes place normally, i.e., in the 1,4-positions, and is so rapid that polymerization (of butadiene) is largely avoided.

$$CH_2{=}CHCH{=}CH_2 + (SCN)_2 \longrightarrow CH_2(SCN)CH{=}CHCH_2(SCN)$$

Interaction of this product with halogens (chlorine or bromine) in acetic acid as a solvent gives rise to 2,3-dihalogenated compounds. With chlorine this may be represented by

$$CH_2(SCN)CH{=}CHCH_2(SCN) + Cl_2 \longrightarrow CH_2(SCN)CHClCHClCH_2(SCN)$$

1,4-Dithiocyanobutene, however, undergoes decomposition when boiled with solutions of caustic soda, one of the substances formed being sodium sulphide.

Reduction of diolefins to monolefins may be effected by treating the former successively with an alkali metal and an amine.[65b] Thus, butadiene may be dissolved in ether at −10° to 20°C., and reacted with lithium and ethylaniline. Under these conditions the product is said to consist mainly of *cis*-1,2-dimethylethylene.

ANALYTICAL REACTIONS OF CONJUGATED DIENES

The use of maleic anhydride as a reagent in the determination of conjugated diolefins in complex gas mixtures has been the object of considerable experimentation.[66] However, its application in a quantitative analysis has been limited. Korotkov[67] has described an apparatus for the determination of butadiene in a gas mixture. The latter, during the course of analysis, passes through a U-shaped tube containing maleic anhydride which is kept in a molten state by immersing the tube in boiling water. The diolefin is absorbed by the condensation with the reagent.

[64] British P. 446,222, 1936, to I. G. Farbenind. A.-G.; *Brit. Chem. Abs.* **B**, 1936, 824; *Chem. Abs.*, 1936, **30**, 6760; French P. 788,341, 1935; *Chem. Abs.*, 1936, **30**, 1387.

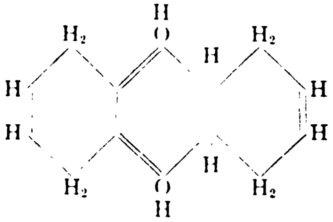
[65] The preparation of butadiene alkoxy derivatives from vinylacetylene has been described by I. A. Rotenberg and M. A. Favorskaya (*J. Gen. Chem.* (*U.S.S.R.*), 1936, **6**, 185; *Chem. Abs.*, 1936, **30**, 4808; *Brit. Chem. Abs.* **A**, 1936, 964).

[65a] E. Müller and A. Freytag, *J. prakt. Chem.*, 1936, **146**, 58; *Chem. Abs.*, 1936, **30**, 7537; *Brit. Chem. Abs.* **A**, 1936, 1228.

[65b] K. Ziegler, F. Häffner and H. Grimm, *Ann.*, 1937, **528**, 101; *Brit. Chem. Abs.* **A** (2), 1937, 173.

Because of its reactivity with other conjugated diolefins, maleic anhydride can be applied only when one particular diolefin is present. For example, Tropsch and Mattox[68] have offered a procedure for quantitatively determining butadiene in gases when no other diolefins are present. These workers found that the presence of monolefins or acetylene in concentrations up to 15 per cent did not influence the accuracy of the analysis. Dolgoplosk[69] has used a rapid hydrogenation method in the analysis of butadiene in gaseous products intended for use in the manufacture of synthetic rubber. In this investigation he passed the gas diluted with hydrogen over a catalyst, either nickel (50 per cent) or palladium (30 per cent) precipitated on asbestos, and observed the change in volume. It was noted that the presence of 0.03 per cent of carbon monoxide caused the catalyst to become poisoned unless the latter was heated.

Butadiene has been determined by condensation with quinones in the presence of other olefins, ether and acetic acid.[70] The gas to be analyzed was conducted through a phenol solution of benzoquinone to furnish a thick black oil, believed to be 1,4,5,8-tetrahydroanthrahydroquinone:



Sorokin and Puzitzkii[71] have shown that the action of liquid sulphur dioxide on butadiene cannot be adapted to the quantitative determination of the latter compound.

The estimation of olefins and diolefins with halogens and halogen acids has been previously proposed.[72] Sorokin, Belikova and Bogdanova[73] report that the method of Ipatieff and Vittorf[74] for the determination of isoprene can be applied to butadiene. The procedure is based on the formation of the monobromide (b.p., 103°C.) and dibromide (b.p., 170-172°C.) of butadiene from the action of hydrobromic acid in glacial acetic acid.[75]

[75] The compounds which have nearly the same composition and have similar boiling ranges are bromocyclobutane (b.p., 102-104°C.) and 1,3-dibromobutane (b.p., 173-174°C.) as reported by W. H. Perkin, Jr. (*J.C.S.*, 1894, **65**, 950; *Chem. Zentr.*, 1895, **1**, 25).

In his study of cyclopentadiene and dicyclopentadiene, Schultze[76] found that these two compounds absorb oxygen within a very short time to such an extent that any quantitative bromination of these hydrocarbons is rendered inaccurate.[77] He stated that the addition of bromine is dependent upon the peroxide content of the material. That is, "no quantitative results are found whenever the experimental conditions are such as to permit peroxide formation previous to bromination." With this in mind, he presented three methods of analysis of cyclopentadiene and dicyclopentadiene. The first of these was a modified bromide-bromate titration using 0.4 *N* sulphuric acid in a vacuum titration bottle. The second was a bromine-water titration also in a vacuum bottle. In the third method, the titration was carried out in the presence of air with an excess of free bromine present in solution before the capsule containing the material to be analyzed was broken.

Cyclopentadiene can be determined in mixtures with its polymers by means of its reaction with *p*-nitrobenzenediazonium chloride in acetic acid solution.[78]

Diazotized *p*-nitroaniline has also been found to react quantatively with conjugated dienes but only when these are admixed with saturated hydrocarbons.[79] The excess diazo reagent is back-titrated with β-$C_{10}H_7OH$. 2,3-Dimethyl-1,3-butadiene, 1,3-cyclohexadiene and cyclopentadiene are among those diolefins which may be estimated in this manner.

A report of a color reaction for the detection of very small quantities of cyclopentadiene has been announced by Afanas'ev.[80] His procedure involves the use of one drop of the specimen mixed with 1 cc. each of chloroform and glacial acetic acid and then treated cautiously with 2 or 3 drops of concentrated sulphuric acid. As little as 0.1 milligram of cyclopentadiene gives a distinct violet coloration.

Chapter 28

Important Reactions of Acetylene

Acetylene, HC≡CH, is the simplest member of the alkyne series of hydrocarbons possessing the general formula C_nH_{2n-2}. Its homologues may be placed roughly into two classes in which one, or both, of the hydrogen atoms of acetylene are replaced by alkyl or aryl groups. Because of its unsaturated and unstable character, acetylene lends itself to a great variety of reactions, making it the starting point for the synthesis of a number of important products.[1]

Although the major proportion of commercial acetylene is obtained by the hydrolysis of calcium carbide, significant quantities can be produced by the electrical and thermal decomposition of gaseous hydrocarbons from petroleum as described in Chapters 4 and 9.[2] To the layman the familiar application of acetylene is as a gas for illuminating purposes and for welding by means of the oxy-acetylene flame,[3] but to the chemist a more interesting use is as raw material for the preparation of a wide variety of organic compounds.[4] Among these are acetaldehyde, acetic acid, acetone, vinyl esters and ethers, acetals and various halogenated hydrocarbons as well as synthetic drying oils, synthetic rubber and synthetic resins.[5] By-products in the acetaldehyde, acetic acid and acetone syntheses include biacetyl, acetonylacetone, 2,5-dimethylfuran, acetylmethylcarbinol, 1,3-butene glycol, ethyl β-hydroxybutyrate and 4-methyl- and 5-methyl-2,3-dihydroxybenzaldehyde.[6] (See Fig. 153)

Acetylene is a colorless gas, possessing a pleasant ethereal odor.[7] Because of its endothermic nature acetylene cannot be stored in cylinders under high pressure but it may be kept under 10 atmospheres pressure by dissolving it in acetone absorbed on a porous mass.[8] The high solubility of the hydrocarbon in acetone, 24 volumes at 15°C. under 1 atmosphere, is of course well known.[9] Proposals for the use of acetone solutions of acetylene with alcohol and with furfural as motor fuels have been made.[10]

---

[1] A review of developments of acetylene chemistry is given by O. Nicodemus, *Angew, Chem.*, 1936, **49**, 787; *Chem. Abs.*, 1937, **31**, 477.

[2] It is interesting to note that an azeotropic mixture of acetylene (40.7 per cent) and ethane (59.3 per cent) has been isolated from reformed refinery gases (W. A. McMillan, *J.A.C.S.*, 1936, **58**, 1345; *Chem. Abs.*, 1936, **30**, 6702).

[3] A comparison of oxyacetylene flames with other fuel gases for cutting purposes has been described by G. V. Slottman (*36th Ann. Convention, Intern. Acetylene Assoc. (Cleveland)*, 1935; *Chem. Abs.*, 1936, **30**, 2149).

[4] For a brief discussion see J. A. Nieuwland, *Ind. Eng. Chem.*, 1935, **27**, 851.

[5] For a discussion of the latter three types of products see Carleton Ellis, "The Chemistry of Synthetic Resins," Reinhold Publishing Corp., New York, 1935.

[7] For an extensive description of the physical and chemical properties of acetylene, see Carleton Ellis, "The Chemistry of Petroleum Derivatives," Chemical Catalog Co., New York, 1934. A method for the determination of small amounts of acetylene in butadiene or nitrogen has been developed by T. F. Chernyakovskaya (*Sintet. Kauchuk*, 1936 (2), 29; *Chem. Abs.*, 1936, **30**, 6309).

[8] See, in this instance, H. P. Rauert, *Azetylene Wiss. Ind.*, 1932, **35**, 97; *Chem. Abs.*, 1934, **28**, 5209. The explosive nature of acetylene has been discussed by W. C. de Liefde (*Chem. Weekblad*, 1934, **31**, 711; *Brit. Chem. Abs.* B, 1935, 835; *Chem. Abs.*, 1935, **29**, 3161) and A. Krauss (*Autogene Metallbearbeit*, 1935, **28**, 72; *Brit. Chem. Abs.* B, 1936, 818; *Chem. Zentr.*, 1935, **2**, 563).

[9] For a discussion of the solubility of acetylene at 50 to 760 mm. pressures in dichloroethane, 97 per cent ethyl alcohol and heavy naphtha (b.p., 150-250°C.) at 0°C. and in kerosene at 0°C. or 20°C., see V. A. Kireev and M. A. Romanchuk (*J. Gen. Chem.* (*U.S.S.R.*), 1936, **6**, 78; *Chem. Abs.*, 1936, **30**, 7421).

[10] J. Arauz, *Anales univ. central Ecuador*, 1933, **50**, 179; *Chem. Abs.*, 1934, **28**, 5955. J. M. H. Classen, German P. 615,651, 1935; *Chem. Abs.*, 1935, **29**, 8294. See also Chapter 44.

Much interest has been shown in the products formed by the reaction of acetylene with salts of mercury, particularly since the latter have been employed as catalysts in the hydration of acetylene to acetaldehyde or its condensation with hydroxy compounds and with organic acids. The composition of the complex salt resulting from the interaction of acetylene and mercuric chloride has caused some controversy. For instance several workers stated that the compound $C_2(HgCl)_2$ was formed.[11] Others reported obtaining a substance $C_2Hg_3Cl_4$ which hydrolyzed rapidly to $C(HgCl)_3CHO$, trichloromercuriacetaldehyde.[12] Later work[13] has indicated the composition of the product to be $HgC_2 \cdot HgCl_2 \cdot HgCl$. When treated with a saturated solution of mercuric acetate in acetic acid, acetylene furnishes the substance $2HgC_2 \cdot C_2H_2 \cdot H_2O$, which although initially of an explosive character loses this property on storage.[14]

FIG. 153.—Acetylene Tree, Showing Variety of Compounds Available from Reactions of Acetylene.

POLYMERIZATION OF ACETYLENE

Polymerization and decomposition of acetylene present a field of chemical investigation in which a wide variety of conditions may be employed. Means of inducing reaction include chemical reagents, heat, electrical discharges, alpha particles, light rays, cathode rays and electromagnetic fields.[15] The products include gases, aliphatic and aromatic liquids, tars and solids. As will be pointed out later, controlled polymerization of acetylene yields unsaturated hydrocarbons (e.g., vinylacetylene) from which numerous diverse compounds can be synthesized.[16]

[14] E. Ferber and E. Römer, *loc. cit.*

According to Toul[17] very pure acetylene does not polymerize when exposed to sunlight. Polymerization does take place, however, in ultraviolet light.[18] Although early investigators reported only solid polymers, later ones have noted the formation of benzene and other aromatic hydrocarbons as well as saturated and olefinic hydrocarbons in this treatment.[19] The empirical formula of the solid product obtained by the action of ultraviolet light on acetylene was calculated by Lind and Livingston[20] to be approximately $(C_{10}H_9)_n$. From this a mechanism of polymerization was suggested as follows:

$$\begin{aligned} C_2H_2 + h\nu &\longrightarrow C_2H_2 \longrightarrow C_2H + H \\ C_2H_2 + C_2H &\longrightarrow C_4H_3 \\ C_4H_3 + C_2H_2 &\longrightarrow C_6H_5, \text{ and so on.} \end{aligned}$$

The formation of benzene and related hydrocarbons was explained by side reactions:

$$\begin{aligned} C_8H_7 &\longrightarrow C_6H_6 + C_2H \\ \text{or } C_6H_5 + H &\longrightarrow C_6H_6 \end{aligned}$$

The polymerization of carefully purified acetylene at 750°C. was studied by Mignonac and Ditz.[21] The gas was passed rapidly through an electrically heated quartz tube and the products were immediately cooled to —70°C. giving a yellow liquid condensate consisting largely of benzene. Other constituents, obtained on fractional distillation of the condensate, included unreacted acetylene and two dimers, one a stable, colorless gas and the other a yellow unstable gas which was given the name "chlorene." It is said that a 90 per cent yield of benzene can be obtained if acetylene is preheated and then mixed with inert gases at 630°C. and the product cooled rapidly.[22] Under these conditions no tarring or carbonization occurs. Investigations of the polymerization of acetylene at 950-1050°C. have shown that the introduction of nitrogen has the same effect as would a reduction of pressure.[23] Hydrogen favors the formation of methane and the presence of the latter retards the development of more methane. This hydrocarbon, when present to the extent of 30 per cent or more, is a factor in the production of light and heavy oils from acetylene. Liquid diluents, for example decahydronaphthalene, may be employed.[24] In such cases reaction may be effected at pressures of 40-50 atmospheres and temperatures of 320-440°C.

---

[15] Pyrolysis of acetylene is discussed in Chapters 2, 4 and 5. For use of electrical energy see Chapter 9.

Simultaneous hydrogenation and polymerization of acetylene with mixed catalysts has been studied by Peters and Neumann.[25] By use of a mixture of 9 parts iron, 0.5 part nickel and 0.5 part copper and employing temperatures up to 190°C., a 64 per cent yield of liquid products resulted. Tungstic oxide, the rare earth oxides and iron oxide were not effective agents, although the latter was rendered active by the addition of nickel monoxide. According to Petrov and Antzus[26] employment of a reduced nickel catalyst yields a gasoline (end point 320°F.) containing about 40 per cent of naphthenic hydrocarbons.

When heated in the presence of copper, its oxides or alloys, acetylene yields a yellow-brown solid polymer of indefinite composition but of an aromatic nature. This material, known as cuprene or carbene, has been the subject of many investigations[27] both as to its nature and as to improvements in its manufacture. Depending upon the use for which it is intended, cuprene may be obtained as a soft, flocculent product or as a hard, brittle, porous mass. For example, acetylene mixed with 10-15 per cent nitrogen is passed over cuprous oxide containing one per cent stannic oxide. Soft products are obtained at 180-245°C. and a brittle material at 250-260°C.[28] Applications of cuprene include its utilization as an absorbent for fuels and illuminants and as a filler for linoleum and plastic masses.

Monovinylacetylene. Properly controlled low-temperature polymerization of acetylene will convert the hydrocarbon into monovinylacetylene, divinylacetylene and a tetramer, C_8H_8. One contact material which may be employed is an aqueous solution containing a mixture of a cuprous salt, an ammonium salt or a tertiary amine, and an inorganic acid.[29] The speed of contact between the hydrocarbon gas and catalyst may be varied so that monovinylacetylene is the main product. In a process developed by Chilton,[30] the resulting gases (containing acetylene and its polymers) are precooled to about 0°C. and dried by calcium carbide. Thus, further polymerization is said to be prevented. Separation from excess acetylene is effected by cooling to $-50°$ to $-80°$C. or by countercurrent extraction of monovinylacetylene with a mineral oil.[31] Modifications of the above-mentioned catalysts include the use of organic acids in place of inorganic[32] and the substitution of water by an inert non-aqueous solvent of high boiling point, e.g., glycerol or ethylene glycol.[33]

Perkins and Toussaint[34] converted acetylene into vinylacetylene by passing the gas at 70°C. into a nearly neutral aqueous solution of an alkali cuprochloride prepared from cuprous chloride and ammonium chloride or a chloride of an alkali metal or alkaline earth metal. With this type of mixture it has been also suggested[35] that the acidity be adjusted to a *p*H of about 6.0. In another method acid cuprous salt solutions free from nitrogen bases and containing salts of the alkali or alkaline-earth metals are employed.[36] The insoluble complex formed when acetylene is led into a solution containing 18 per cent cuprous chloride and 20 per cent ammonium chloride is said[37] to have the composition $6CuCl \cdot 3NH_4Cl \cdot C_2H_2$.

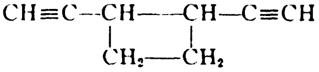
By passing acetylene at 300-800°C. over a catalyst, such as gold, molybdenum, silver or their alloys, or oxides of titanium, uranium or zirconium, monovinylacetylene and some aromatic compounds were formed.[38] Reaction may be effected by using a solid catalyst of a cuprous compound and a salt of an alkali or alkaline earth metal or ammonium salt.[39] With cuprous chloride and ammonium chloride precipitated on pumice, a 5 per cent yield of vinylacetylene (based on the acetylene used) was obtained at 200-250°C. At 350-400°C. the same yield was reported, using zinc chloride on pumice.[40]

According to Dykstra,[41] vinylacetylene can undergo at least three distinct types of polymerization. When heated without a catalyst at 105°C. for 6 hours, monovinylacetylene yields a mixed polymer in the form of a soft resin containing approximately 1 per cent dimer, 3 per cent trimer, 16 per cent tetramer, 8 per cent pentamer and 72 per cent higher polymers. The dimer in this case was thought to be diethinylcyclobutane:



$$\begin{array}{c} CH{\equiv}C{-}CH{-}{-}{-}CH{-}C{\equiv}CH \\ \quad\;\;\, | \qquad\quad | \\ \quad\;\;\, CH_2{-}{-}{-}CH_2 \end{array}$$

A similar thermal treatment of vinylacetylene with 1 to 10 per cent of acidic materials resulted in a 20-50 per cent yield of styrene. With cuprous chloride as catalyst, a dimer, 1,5,7-octatriene-3-yne, is formed.

With the aid of salts of mercury, silver, cadmium, copper or zinc in an acid solution (e.g., sulphuric, acetic, phosphoric), vinylacetylene can be hydrated to methyl vinyl ketone.[42] The reaction is assisted, according to Conaway,[43] by an oxidizing agent, e.g., ferric sulphate or oxide, copper sulphate, chromates, manganates and vanadates. A polymerization inhibitor, e.g., pyrogallol, eugenol or guaiacol, may be employed during distillation of the ketone. Using sodium alcoholates as catalysts, alcohols can be made to add smoothly to vinylacetylene at about 100°C. to give unsaturated ethers of the general formula $CH_3C{\equiv}CCH_2OR$. Thus, for example, ethyl alcohol adds to form 4-ethoxy-2-butyne.[44] If a contact mixture of boron fluoride, mercuric oxide and trichloroacetic acid is employed, vinylacetylene readily adds three molecules of methyl alcohol, forming 2,2,4-trimethoxybutane, $CH_3O—CH_2—CH_2—C(OCH_3)_2CH_3$. The latter compound hydrolyzes to give a 75 per cent yield of 4-methoxybutan-2-one.[45]

Rotenberg and Favorskaya[46] have investigated the interaction of vinylacetylene with alcohols in the presence of potassium hydroxide. In the case of ethyl alcohol, the mixture, after being heated for 10 hours at 140-150°C. in an autoclave, gave a 70 per cent yield of 2-ethoxy-1,3-butadiene (b.p. 113-117°C.).

$$HC\equiv C—CH=CH_2 + C_2H_5OH \xrightarrow{KOH} CH_2=C(OC_2H_5)CH=CH_2$$

When reacted with methyl alcohol in the presence of the same alkali for 18 hours at 150°C., monovinylacetylene yielded 70 per cent of 1-methyl-1-methoxyallene (b.p., 92-100°C.).

$$HC\equiv C—CH=CH_2 + CH_3OH \xrightarrow{KOH} CH_2=C=C(OCH_3)CH_3$$

However, in the absence of the alkali hydroxide and at 100-150°C., styrene ($CH_2=CHC_6H_5$) was obtained probably as the condensation product of 2 molecules of vinylacetylene.

The addition of carboxylic acids to vinylacetylene yields esters of 1,3-butadiene-2-ol.[47] The reaction is catalyzed by a mercuric salt or by boron fluoride. For instance, 1,3-butadienyl-2-acetate may be prepared by reacting vinylacetylene with acetic acid in the presence of a mercuric sulphate-sulphoacetic acid catalyst. This ester and the corresponding formic, chloroacetic and butyric esters polymerize on standing, forming rubber-like and resinous materials.

The above-mentioned esters are analogues of chloroprene, 2-chloro-1,3-butadiene, obtained by the addition of hydrogen chloride to vinylacetylene, particularly in the presence of cuprous chloride.[48] A water-immiscible liquid, e.g., toluene, may be employed as a solvent for removing the products in this type of reaction.[49] Chloroprene is of interest because of the commercial use of its polymer, α-polychloroprene, as a synthetic rubber marketed as Neoprene.[50]

In a similar manner, hydrogen halides add to substituted monovinylacetylenes of the general formula $CH_2=CH—C\equiv C—R$ to give products analogous in character to chloroprene and capable of polymerization to rubber-like masses.[51]

Reaction of alkaline hypohalites with vinylacetylene at about 0°C. yields 1-halogeno-2-vinylacetylenes.[52] These are described as liquids with characteristic, sickening odors. Polymerization takes place on standing, forming explosive black solids. Treatment of the chloro compound, 1-chloro-2-vinylacetylene, with hydrochloric acid furnishes 1,2-dichloro-1,3-butadiene which polymerizes spontaneously to a rubber-like material.[53]

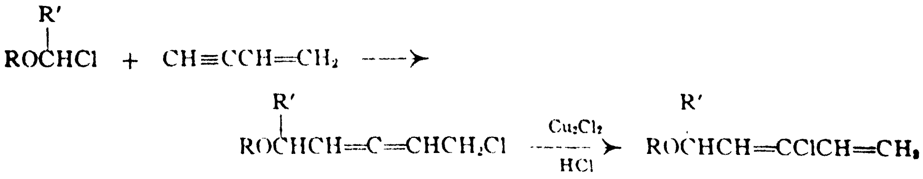
Dykstra[54] found that alpha chloroethers combine with vinylacetylene in a manner closely analogous to the addition of hydrogen chloride to vinylacetylene to form isochloroprene and chloroprene. A 1,4-addition (in diethyl ether) apparently takes place and is followed by isomerization in the presence of cuprous chloride and hydrochloric acid. The following general equations may represent these reactions.

Courtesy E. I. du Pont de Nemours & Co.

FIG. 153A.—Manufacture of Neoprene. At this stage the chloroprene rubber greatly resembles crude natural rubber.



$$\mathrm{RO\overset{R'}{C}HCl} + \mathrm{CH{\equiv}CCH{=}CH_2} \longrightarrow$$

$$\mathrm{RO\overset{R'}{C}HCH{=}C{=}CHCH_2Cl} \xrightarrow[\mathrm{HCl}]{\mathrm{Cu_2Cl_2}} \mathrm{RO\overset{R'}{C}HCH{=}CClCH{=}CH_2}$$

[53] A. L. Klebanskii, A. S. Volkenshtein and A. P. Orlova, *J. Gen. Chem.* (*U.S.S.R.*), 1935, **5**, 1255; *Chem. Abs.*, 1936, **30**, 1025.

[54] H. B. Dykstra, *J.A.C.S.*, 1936, **58**, 1747; *Chem. Abs.*, 1936, **30**, 7537.

In this way, Dykstra obtained 5-methoxy-1-chloro-2,3-pentadiene and 5-methoxy-3-chloro-1,3-pentadiene from chloromethyl methyl ether (where R is a methyl group and R′ is a hydrogen atom).

Vinylacetylene will react with Grignard reagents to form the corresponding magnesium compound, which in turn reacts with ketones, aldehydes, carboxylic acids, nitriles, isocyanates, halides and ethers to give various vinylacetylene derivatives.[55] Thus, vinylacetylene and ethylmagnesium bromide give vinylethinylmagnesium bromide, which with acetone yields vinylethinyldimethylcarbinol, $CH_2{=}CHC{\equiv}CCOH(CH_3)_2$. Compounds of this type may be synthesized also by converting vinylacetylene with alkali metals or alkali metal amides into vinylacetylides which are then treated with ketones.[56] Polymerization of vinylethinylcarbinols (accelerated by the action of air or light) yields tough or hard transparent masses which are suggested for use in coating compositions, safety glass and molding preparations.[57]

Vinylacetylene and potassium mercuri-iodide or mercuric acetate in acetic acid at room temperature form divinylethinylmercury. The latter reaction at 60-70°C. results in a 93 per cent yield of 1,1-diacetoxymercuri-2-acetoxymercurioxy-1,3-butadiene,

$$CH_2{=}CH(CH_3COOHgO)C{=}C(HgOOCCH_3)_2.$$

which is decomposed by hydrochloric acid to methyl vinyl ketone.[58] By leading vinylacetylene into an acid solution of a mercuric salt (e.g., mercuric sulphate in sulphuric acid) and subsequently decomposing the resultant mercury compound with hydrochloric acid at 90-100°C. biacetyl is produced.[59] Utilization of the latter compound as a flavoring agent in butter substitutes has been suggested.[60] Monovinylacetylene in compressed or liquid form has been proposed as a combustion gas for such industrial purposes as welding, heating and illumination.[61]

Divinylacetylene. As mentioned previously, divinylacetylene is formed by the same methods employed for monovinylacetylene, the divinyl compound being a trimer of acetylene whereas monovinylacetylene is the dimer.[62] The trimer is quite unstable; on exposure to air it is transformed into a dangerously explosive, soft jelly-like mass. The pure compound decomposes at 105-110°C., but below this temperature it is capable of polymerizing in an inert atmosphere to yellow, viscous liquids or hard, insoluble resins.[63] Because of the ability of these viscous liquids to polymerize further to form hard, chemically resistant films they have been employed as synthetic drying oils.[64] Partial hydrogenation of divinylacetylene before polymerization is said to increase the stability of its polymers to light.[65] From the oily polymers, Cupery and Carothers[66] isolated a dimer, trans-1,2-bis(vinylethinyl)cyclobutane,

The presence of a trimer, a bis(vinylethinylcyclobutyl)acetylene in the oily mixture was postulated.

Chlorine reacts with divinylacetylene by 1,4 addition to yield a dichloride and then a tetra- and hexachloride.[67] By the action of hydrochloric acid at room temperature a dihydrochloride, 1,3-dichloro-2,4-hexadiene is formed.[68] In both of these reactions all unsaturated linkages are involved. Combination with thio-*p*-cresol, however, involves only the ethylene linkages, giving rise to 1,6-bis(*p*-tolylthio)-3-hexine.[69] Hydration of divinylacetylene furnishes vinyl allyl ketone (b.p. 85-86°C. at 20 mm.) an oily liquid with a sharp odor.[70] Treatment of divinylacetylene with a hydrogen polysulphide at temperatures of —10 to 10°C. is said to give resinous materials applicable as paint and lacquer vehicles.[71] Products of a resinous or viscous oily nature, which in air dry to resistant films, may be procured by simultaneous reaction of hydrogen sulphide and sulphur with mono- or divinylacetylene in the presence of a catalyst of dibutylamine, aniline or pyridine.[72]

HALOGEN DERIVATIVES OF ACETYLENE

Of the various halogen derivatives of acetylene, those containing chlorine are the most important. The ultimate product of the chlorination of acetylene is acetylene tetrachloride (tetrachloroethane) from which several chlorinated solvents, particularly trichloroethylene, $CHCl=CCl_2$, can be made.

Continuous production of acetylene tetrachloride in 95-98.5 per cent yield has been described by Favorskii, Margules and Davuidova.[73] Dry acetylene and chlorine are fed into the top of a jacketed iron column completely filled with iron shavings. Acetylene tetrachloride is sprayed in under pressure, and this, plus an additional amount formed in the reaction, drips into a receiver filled with pebbles to facilitate the trapping of gases. Temperatures of 60-70°C. were recommended. A 90 per cent yield is said to be possible at 70-75°C. but at 100°C. considerable hexachloroethane is formed.[74]

Chlorination of acetylene-hydrogen mixtures (e.g., from decomposition of methane) to acetylene tetrachloride, $CHCl_2CHCl_2$, has been carried out at 100-

200°C. using as catalysts iron compounds on a carrier of silicates or silica gel.[75] It is stated that formation of hydrogen chloride is avoided in the chlorination of cracked gases containing acetylene if temperatures of 80-140°C. are employed.[76]

On dechlorination by various means, e.g., by action of alkalies or by catalytic decomposition, acetylene tetrachloride is converted into trichloroethylene.[77] Because of its powerful solvent action, low surface tension and high penetration, this trichloro derivative has found a number of uses.[78] For instance, it has been employed as an extracting agent in the winning of vegetable oils, e.g., soya bean oil,[79] and in the decaffeination of coffee beans.[80] Its high specific gravity (1.47) and low specific heat and heat of vaporization have made trichloroethylene useful in dewaxing petroleum oils by centrifugal means.[81] This compound has also been employed as a constituent of insecticidal sprays[82] and polishes for floors, furniture, boots and shoes,[83] and a grease solvent in the cleaning of metal pipes.[84]

Because of the varied applications of trichloroethylene, its stability and corrosive action are of interest. Carlisle and Levine[85] state that it is not corrosive if antioxidants are present and that even in their absence action is only slight.[86] The compound is quite stable to light unless oxygen is present. Decomposition by action of light is also prevented by the addition of antioxidants. Among the substances proposed as stabilizers for trichloroethylene are alkylamines and benzylamines, diphenylguanidine,[87] triethylamine,[88] amylene,[89] mercaptans,[90] phenolic substances[91] and caffeine.[92] The toxicity of trichloroethylene has been noted by many workers[93] although in some cases the compound has served as an anesthetic.[94] Mercury trichloroethylenide may be prepared by agitating trichloroethylene with an aqueous alkaline solution of an alkali metal cyanide to which a paste of freshly precipitated mercuric oxide has been added.[95]

In addition to its possible use as an anesthetic, trichloroethylene has also been suggested as a remedy for migraine (severe headache). Geiger and Goodman,[95a] however, relate they did not obtain favorable results with this halogenated olefin, as only a small proportion of patients treated experienced relief.

It is reported that trichloroethylene heated with metals such as zinc, iron and cadmium in the presence of water yields dichloroethylene.[96] Conversion of either geometrical isomer of 1,2-dichloroethylene into the other is said to occur on treatment with a small proportion of bromine in the presence of antimony bromide.[97]

The photobromination of acetylene at 150°C. yields dibromoethylene, according to Booher and Rollefson.[98] To produce *sym*-tetrabromoethane, acetylene may be led into aqueous solutions containing bromides to which chlorine water has been added to form free bromine.[99]

Although many investigators have reported that very little or no action takes place in the cold between acetylene and iodine, Ellis[100] noted that almost complete conversion to acetylene diiodide ($C_2H_2I_2$, diiodoethylene) was effected in 2-3 days at 25°C. in a container whose inside surface was coated with sublimed iodine. Previous workers[101] found that reaction of acetylene with iodine (most favorably at 140-160°C.) gives a mixture of two isomeric 1,2-diiodoethylenes. Kaufmann[102] has stated that the action of metallic sodium on 1,2-diiodoethylene (acetylene iodide) in ether solution causes the formation of 1,1-diiodoethylene. This statement was refuted by Emschwiller[103] who believed that such a reaction resulted in a 30 per cent conversion to diiodoacetylene, $CI{\equiv}CI$, the remainder being unchanged diiodoethylene. Vaughn and Nieuwland[104] obtained diiodoacetylene by iodination of acetylene or of sodium acetylide in liquid ammonia. Dehn[105] prepared the same compound by action of sodium hypoiodite (from sodium hypochlorite and potassium iodide) on acetylene. Reaction of iodine with sodium acetylide in benzene has yielded triiodoethylene and tetraiodoethylene.[106] Mono- and diiodoacetylene may be formed by the action of iodo-silver benzoate on acetylene.[107]

HYDRATION OF ACETYLENE TO ACETALDEHYDE

Of the many chemical reactions of acetylene perhaps the most important is its hydration to acetaldehyde. The latter can then be employed in the manufacture of acetone, acetic acid, crotonaldehyde, ethanol, butanol, butyric acid and ethyl acetate as well as many other products, including synthetic resins.[108]

The usual industrial method for hydration of acetylene consists in conducting the gas through an acid solution containing a catalyst. One procedure has been described by Thommen.[109] A large excess of acetylene is passed continuously through an apparatus filled with 30 per cent sulphuric acid maintained at 60-70°C. A steady stream of mercuric oxide suspended in water is fed into the acid, which is kept well agitated. Water vapor and the acetaldehyde formed are carried along with the gas stream which is run through condensers and washers to remove acetaldehyde. Unreacted acetylene is then returned to the reaction vessel to repeat the cycle. The aldehyde water from the washers contains 10-20 per cent of acetaldehyde, which is recovered by rectification. Sludge formation and consumption of mercuric oxide are minimized by use of purified acetylene.

A number of catalysts have been proposed for the hydration of acetylene in both the liquid and gaseous phases.[110] Millar and Steck[111] suggested a solution containing a free acid, a mercury compound and an acid salt of an alkali metal or of ammonia. Rosinsky and Baumann[112] have passed acetylene into concentrated aqueous solutions of normal salts with acid reaction, e.g., the halides of zinc, chromium, cadmium, iron, magnesium and calcium. Yields are said to be increased by the use of promoters, e.g., mercury compounds and water-soluble salts of uranium, gold and platinum. For vapor-phase hydration, acetylene and water vapor may be passed over tungstic oxide or sulphide, tungstic acid or ammonium tungstate at 300-400°C. Activators, such as zinc oxide or selenide, copper oxide and cobalt sulphide may be incorporated with the catalyst.[113] For this type of hydration, aluminum oxide may be employed, with oxides or sulphides of cadmium and zinc or with chromates, tungstates or molybdates as dehydrogenating catalysts.[114] Also, the use of a mixture of phosphates of cadmium and an alkaline earth metal (e.g., calcium) has been proposed, temperatures of 250-400°C. being employed.[115]

Catalytic hydration of acetylene may also be carried out in two stages, the first in liquid phase and the second in gaseous phase.[116] In the first stage, a portion of the hydrocarbon is converted to acetaldehyde by passing through an acid (for example, sulphuric acid) containing mercury, usually as mercurous sulphate. The unchanged acetylene is converted in the gaseous phase by catalytic reaction with steam.[117] To make acetaldehyde distillation-stable in monomeric or trimeric form it may be treated with acid-binding substances, e.g., sodium acetate.[118]

Although acetic acid can be made from acetaldehyde by oxidation,[119] numerous methods have been proposed for its manufacture directly from acetylene.[120] In one such procedure a mixture of acetylene, water vapor and oxygen is saturated with mercury vapor and passed over a porous body carrying a hydration catalyst, e.g., phosphoric acid and zinc oxide, or ferric hydroxide or vanadium oxide. By using active carbon and mercuric phosphate a yield of 60 per cent acetic acid and 14 per cent acetaldehyde has been reported.[121] Acetaldehyde, acetone and acetic acid

may be obtained by conducting acetylene and steam at 300-450°C. through a fused salt with acid reaction. A mixture of zinc chloride and aluminum chloride may be employed.[122] Catalysts for the reaction include the oxides of cerium, chromium, barium, zinc and titanium mixed with potassium hydroxide or sodium silicate.

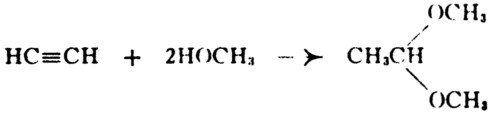
Under proper conditions, acetone may be synthesized from acetylene and steam or from acetaldehyde and steam. For example, reaction between acetylene and water vapor to form acetone may take place at 250-700°C. under 3-10 atmospheres pressure, and catalyzed by oxides of iron, manganese, cobalt, thorium, cerium or tin, or dusty iron sponge impregnated with iron and manganese acetates.[123] Roka and Wiesler[124] suggest reaction of one part acetylene with 5 to 15 parts steam at 300-600°C. in contact with a mixture of oxides having a partial pressure of oxygen within the range 10^{-25} to 10^{-32} atmospheres.

Zelinski and co-workers[125] investigated the use of an iron-manganese catalyst in the synthesis of acetone. With a composition consisting of 7 parts ferric oxide and 3 parts manganese dioxide, acetaldehyde and steam at 400-440°C. gave a 96 per cent yield of acetone. On the other hand, a yield of 88 per cent was obtained with acetylene and steam although this could be raised to 98 per cent by passing the reacting gases over the contact agent a second time. Acetone in 89 per cent yield has been reported from the reaction of acetylene and steam at 450°C. with a catalyst of 4 parts zinc oxide and one part manganous oxide.[126] A possible mechanism for the above reactions is, acetylene first reacts with water to form acetic acid, which then is converted into acetone.[127]

According to Walter,[128] acetone may be synthesized by passing a mixture of acetylene and steam over active carbon impregnated with barium and zinc compounds at 400°C. or with zinc and calcium compounds at 500°C. Yields of 90 per cent are reported.

CONDENSATION OF ACETYLENE WITH HYDROXY COMPOUNDS

By use of catalysts, acetylene may be condensed with alcohols and related hydroxy compounds to form acetals. Thus, methanol reacts with acetylene in the presence of mercuric chloride to form dimethyl acetal.[129]



$$HC{\equiv}CH + 2HOCH_3 \longrightarrow CH_3CH(OCH_3)_2$$

Cyclic acetals result when polyhydric alcohols are substituted for monohydric and mercuric sulphate and concentrated sulphuric acid used as catalyst.[130] It is reported that by this method good yields of cyclic ethylidene derivatives of ethylene glycol, trimethylene glycol, propene glycol, 1,4-tetramethylene glycol, glycerol, glycerol-α-bromohydrin, pinacol and α-methyl glucoside have been obtained. In order to reduce tar formation, Mitchell[131] employed acid-free, freshly precipitated mercuric sulphate. Another catalyst proposed is a mixture of a mercuric compound and fluoboric or fluosilicic acid.[132]

Resinous products result from the condensation of phenol or cresols with acetylene.[133] With β-naphthol, an acetal together with some ethylidene di-β-naphthol is secured. Reaction of acetylene with resorcinol is said to give first vinylresorcinol and then ethylidene diresorcinol. The latter loses water to form dihydroxymethylxanthene, which on oxidation yields hydroxymethylfluorene.[134]

Acetals, on treatment with the proper catalysts, yield unsaturated ethers. For example, acetal vapors may be led at 200-350°C. over finely divided gold, silver, platinum or palladium mixed with auxiliary agents, e.g., copper, aluminum, calcium, zinc, thorium, tungsten, manganese or their oxides, phosphates or silicates.[135] By the reverse reaction, combination of unsaturated ethers with alcohols, acetals may be formed.[136] Vinyl ethers are of interest because of their tendency to polymerize to resinous materials useful in such products as adhesives and lacquers.[137] Divinyl ether, prepared by the action of potassium hydroxide on β,β'-dichloroethyl ether, is used to some extent as an anesthetic.[138]

Reppe[139] has produced vinyl ethers by the action of acetylene on monomeric hydroxy compounds at 80-250°C. in the presence of alkaline catalysts. For example, *n*-butanol and acetylene (potassium hydroxide as catalyst) at 150°C. furnish vinyl butyl ether in 95 per cent yield.[140] Likewise ethylene glycol and acetylene at 120°C. give 33 per cent of ethylene glycol monovinyl ether, 10 per cent of ethylene glycol divinyl ether and 50 per cent of unchanged glycol. In an analogous manner mercaptans unite with acetylene to form vinyl thioethers.[141] Vinyl phenyl ether may be prepared in the vapor phase at about 270°C. from acetylene and phenol, employing a zinc or cadmium salt, e.g., zinc acetate, as catalyst.[142] Vinyl ethers of aromatic hydroxyalkylamines are formed by reaction of the latter with acetylene, using alkaline catalysts.[143]

CONDENSATION OF ACETYLENE WITH HYDROGEN HALIDES

Acetylene and hydrogen halides (in molecular proportions) yield vinyl halides; the latter may react with the halogen halide giving rise to ethylidene dihalides. Perkins[144] made vinyl chloride by passing acetylene at 65°C. into a solution containing 12 per cent hydrochloric acid and 40 per cent catalysts, e.g., equal proportions of cuprous chloride and calcium chloride. Mercuric chloride and anhydrous stannic chloride were used by Toussaint.[145] Baxter[146] employed active carbon, in this instance the catalyst being activated (and reactivated) by a stream of the halide. Reaction temperatures of 100-300°C. and activation temperatures of 200-600°C. were employed. A mixture of vinyl chloride and acetylene is made by the pyrolysis of ethylene dichloride (with inert diluents) at 800-1000°C. Short heating (1-2 sec.) is said to favor the formation of vinyl chloride; diluents, reduced pressure and longer heating (6-8 sec.) promote acetylene formation.[147]

As mentioned previously, vinyl chloride and hydrogen chloride yield ethylidene chloride (*asym.*-dichloroethane). Among the catalysts proposed for this reaction are included the chlorides of aluminum,[148] mercury and zinc.[149] The use of aluminum chloride or ferric chloride in a non-aqueous liquid has also been suggested.[150] According to Kharasch and his associates,[151] hydrogen iodide combines with vinyl chloride to form only ethylidene chloroiodide. Addition of hydrogen bromide to vinyl bromide and to vinyl chloride is influenced by the conditions of the reaction. The presence of peroxides causes the formation of ethylene bromide and bromochloride, respectively. Under peroxide-free conditions the ethylidene compounds are obtained.

Reaction of vinyl chloride with chlorine is said to yield 1,1,2-trichloroethane.[152] Vinyl halides when treated with aqueous solutions of halogens, hypohalogenated acids, hydrogen halides or organic hypohalites form products suggested for refining of mineral oils and purification of gases and also for the manufacture of synthetic resins.[153] Treatment of acetylene with hydrogen fluoride at 0 to 10°C. yields fluorinated compounds which may be employed as insecticides or disinfectants.[154]

CONDENSATION OF ACETYLENE WITH ORGANIC ACIDS

Analogous to the reaction of acetylene with hydrogen halides is its condensation with organic acids to give vinyl esters and ethylidene diesters. Of the vinyl esters, the acetate is of interest since it can be polymerized alone or co-polymerized with vinyl chloride to form light-colored synthetic resins.[155] In the addition of acetic acid to acetylene, conditions must be carefully regulated if vinyl acetate is the product desired, since the latter tends to react with more acetic acid to form ethylidene diacetate. For liquid-phase production, acetylene is conducted into acetic acid in the presence of a catalyst, the temperature being kept relatively low (not above 60°C.). Excess acetylene, passing through the acid, carries with it most of the vinyl acetate formed together with some acetic acid. One type of catalyst consists of a mercury salt of a disulphonic acid, e.g., methionic, $CH_2(SO_3H)_2$, or benzenedisulphonic acid.[156] Another agent which may be employed is mercuric orthophosphate, prepared by dissolving phosphoric acid and mercuric oxide in the carboxylic acid involved in the reaction.[157] Boron fluoride and hydrofluoric acid have been suggested as promoters for mercury catalysts.[158]

The vapor-phase synthesis of vinyl acetate has been studied by Ushakov and Feinstein.[159] It was pointed out by these workers that liquid-phase reaction is disadvantageous because of the continued presence of excess acetic acid, which favors transformation of vinyl acetate into ethylidene diacetate. With both reactants in the vapor phase it is possible to have an excess of acetylene at all times and thus promote formation of vinyl acetate. The best yields (77-84 per cent) were obtained with 9 parts of acetylene to one of acetic acid led through a reaction tube containing the catalyst. When the latter consisted of zinc or cadmium acetate on activated carbon, a temperature range of 180-250°C. was found most satisfactory.

As previously stated, the ultimate reaction products of acetylene and organic acids are ethylidene diesters. Thus, acetylene passed into warm acetic acid (containing catalysts) gives ethylidene diacetate. For this reaction, Walter[160] proposed a catalyst of silica gel added to a solution of mercuric oxide in sulphuric acid. Rabald[161] suggested a mixture of a mercuric sulphonate and a free disulphonic acid. According to Kuwata and Kato,[162] the efficiency of a catalyst of mercuric sulphate is increased if it is precipitated on Japanese acid clay. This is done by adding fuming sulphuric acid to a mixture of the clay and an acetic acid solution of mercuric acetate. Alkylidene diesters may be formed by passing an acetylene hydrocarbon and an aliphatic acid, both in the vapor phase, through a tube containing pumice and zinc acetate.[163] In the case of ethylidene acetate, the temperature employed was 210-215°C.

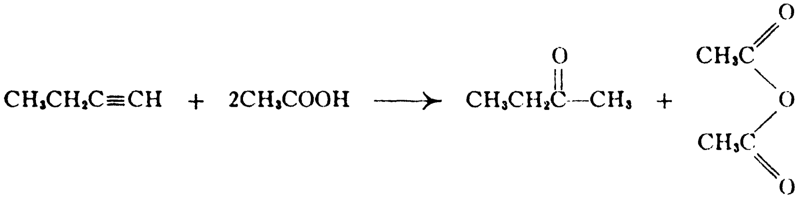
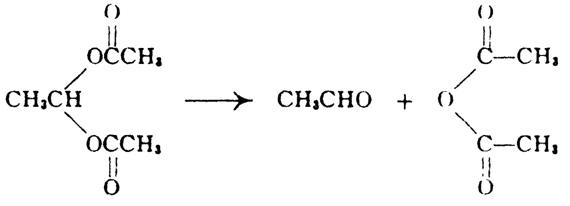
By the reaction of acetylene homologues with aliphatic carboxylic acids it is reported that the anhydride of the acid and a ketone corresponding to the acetylene homologue are obtained.[164] Thus, acetic acid and ethylacetylene would react to form acetic anhydride and methyl ethyl ketone.



CH₃CH₂C≡CH + 2CH₃COOH ⟶ CH₃CH₂C(=O)—CH₃ + CH₃C(=O)—O—C(=O)CH₃

Catalysts include salts of mercury, zinc and cadmium mixed with sulphuric or phosphoric acid.

Acetic anhydride and acetaldehyde are produced by the thermal decomposition of ethylidene diacetate[165] according to the reaction:



Müller and Rabald[166] employed silica or alumina gel (treated with aqueous ammonia, hydrochloric acid or active carbon) as carriers with platinum catalysts for the conversion of ethylidene diesters into acid anhydrides. For the same purpose, metals of groups Ib or VIII (except iron, cobalt and nickel) with roughened surfaces have been proposed.[167] Vinyl acetate reacts with liquid hydrogen chloride under atmospheric pressure to give α-chloroethyl acetate in 50-70 per cent yield.[168]

MISCELLANEOUS REACTIONS OF ACETYLENE

The condensation of acetylene with benzene was apparently first studied by Varet and Vienne.[169] They reported that treatment of 200 parts of benzene and 50 parts of aluminum chloride with acetylene yielded a product containing 80 per cent styrene, 15 per cent *asym*-diphenylethane and 5 per cent bibenzyl (*sym*-diphenylethane). Parone[170] stated that ethylbenzene, styrene, bibenzyl and anthracene were produced by this reaction. Cook and Chambers,[171] in attempting to repeat the work of Varet and Vienne, obtained mainly *asym*-diphenylethane and 9-10-dimethylanthracene hydride (10 parts of each from 200 of benzene) with only traces of styrene. Condensation with toluene gave *asym-p.p*-ditolylethane and 2,7-

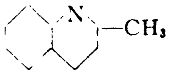
dimethylanthracene (5 parts of each from 200 of toluene) along with small amounts of 2,6-dimethylanthracene and β-methylanthracene. Side reactions yielded xylene, mesitylene and psuedocumene. With the aid of a mercury salt in sulphuric acid, condensation of acetylene with benzene, toluene and ethylbenzene at 10-20°C. has produced ditolylethane (45-50 per cent yield), dixylylethane (50-55 per cent yield) and ethylidene bis-ethylbenzene (20-25 per cent yield) respectively, together with various anthracene derivatives.[172] It has been suggested that petroleum fractions containing aromatic hydrocarbons (e.g., those from Borneo crude) can be refined by treatment with acetylene hydrocarbons at temperatures up to 50°C., in the presence of a diluent (e.g., petroleum ether or cyclohexane) and with the aid of a condensing agent, e.g., boron fluoride or the chlorides of aluminum, iron or zinc.[173] Solid resinous products obtained thereby are said to be applicable in the varnish industry.

Reduction of acetylene by hydrogenation yields first ethylene[174] and then ethane. Reduction to ethylene may also be effected by slightly acid solutions of chromous salts.[175]

Reaction of acetylene with ammonia or amines at elevated temperatures will yield nitriles and pyridine bases. Temperatures of 200-600°C. may be employed and catalysts proposed include non-reducible metal oxides or other compounds such as those of zinc, thorium, vanadium and tungsten or certain free metals, e.g., cadmium, gold, platinum or palladium.[176] This type of synthesis may also be carried out below 200°C. by use of high pressures.[177] Catalytic agents suggested are oxides, hydroxides, alcoholates or anhydrous salts of metals of the first three periodic groups. Thus, ammonia and acetylene heated with zinc chloride at 170-180°C. under 25 atmospheres pressure gave a product believed to be trimethylpyridine. Condensation of acetylene with aniline has been catalyzed in toluene by cuprous or cupric chloride. Kozlov and Fedoseev[178] report that a white solid was produced, which, on distillation, yielded quinaldine,



aniline and a mixture of secondary amines consisting chiefly of tetrahydroquinaldine.

N-Vinyl compounds may be prepared by heating pyrrole (or its derivatives) and acetylene to 100-200°C. under pressure. Alkaline catalysts are suggested. In this manner, N-vinylcarbazole, N-vinylpyrrole and N-vinylindole have been synthesized.[179]

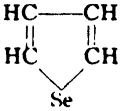
Acetylene and sulphur at 290-390°C., according to Bhatt and co-workers,[180] gave, in addition to a residue of carbon, a brown liquid containing carbon disulphide, thiophene and thiophenol. Meyer and Sandmeyer[181] obtained carbon, hydrogen sulphide, carbon disulphide and a small amount of thiophene by passing acetylene through molten sulphur.[182] Investigation of the effect of various temperatures was undertaken by Peel and Robinson,[183] the best yield (12 per cent) of thiophene being obtained at 500°C. By an analogous reaction of acetylene and selenium at 400°C., selenophene, is formed, together with naphthalene, anthracene, phenanthrene and stilbene.[184] A liquid believed to be tellurophene (tellurium analogue of thiophene) has been prepared by heating acetylene, aluminum telluride and bauxite to 350-600°C.[185]



Thiophene also results from the reaction of acetylene with hydrogen sulphide. Meyer and Wesche[186] reported that at 640-660°C. small amounts of thionaphthene, C_8H_6S, and thiophthene, $C_6H_4S_2$, were formed in addition to thiophene. Acetylene, hydrogen sulphide and purified coal gas (largely methane) gave α- and β-thiotolene. The use of oxides of aluminum, iron, chromium, nickel, titanium, zinc and thorium as catalysts was studied by Chichibabin.[187] With these contact agents 2 volumes of acetylene and one volume of hydrogen sulphide at 425-450°C. gave thiophene (35 per cent of total yield), ethyl mercaptan, *sec*-butyl mercaptan and α- and β-ethylthiophene. Tomkinson[188] pointed out that sulphides rather than oxides are the catalysts in the above reaction, since in every case the oxide is converted to the sulphide with the formation of water. Using ferric oxide as contact agent one volume of hydrogen sulphide and two volumes of acetylene at 300-350°C. yielded an oily liquid containing acetaldehyde and thiophene (30-40 per cent) and its homologues. The ferric oxide "catalyst" was largely converted to the sulphide during the reaction. Acetylene in contact with iron pyrites at 280-310°C. formed a dark condensate 40 per cent of which was thiophene.[189]

Liquid hydrogen sulphide and gaseous acetylene give a small percentage of thioacetaldehyde, according to Guest.[190] Reaction of hydrogen sulphide in aqueous solution with acetylene under 10-20 atmospheres pressure and at 100°C. is said to form α-trithioaldehyde. Ethyl mercaptan and vinylethyl sulphide result if equal volumes of hydrogen sulphide and acetylene are passed through diethylene glycol containing a small percentage of potassium hydrosulphide.[191] With an excess of acetylene the main product is the diethyl ether of ethanedithiol.

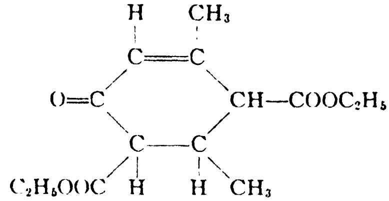
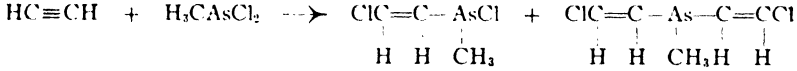
Gustafson[192] pointed out that acetylene reacts at 70-80°C. with ethylacetoacetate in the presence of mercuric sulphate and sulphuric acid. The products obtained were identified as ethyl 3,5-dimethyl-2-cyclohexene-1-one-4-carboxylate (b.p., 102-104°C. at 0.12 mm.) and diethyl 3,5-dimethyl-2-cyclohexene-1-one-4,6-dicarboxylate (b.p., 128-130°C. at 0.12 mm.). The latter compound is represented below:



According to Das-Gupta,[193] acetylene reacts with dichloromethylarsine, CH_3-$AsCl_2$, in the presence of anhydrous aluminum chloride at 10-15°C. The products, β-chlorovinylmethylchloroarsine (b.p. 112-115°C. at 10 mm.) and β,β-dichlorovinylmethylarsine (b.p., 140-145°C. at 10 mm.) are shown in the following equation representing the reaction:



$$HC\equiv CH + H_3CAsCl_2 \longrightarrow \underset{H}{ClC}=\underset{H}{C}-\underset{CH_3}{As}Cl + \underset{H}{ClC}=\underset{H}{C}-\underset{CH_3}{As}-\underset{H}{C}=\underset{H}{C}Cl$$

The second product was also obtained by further reacting the first product with acetylene at 5 to 10°C., using the aluminum chloride catalyst.

Dimethylethinylcarbinol, $CH\equiv CC(CH_3)_2OH$, is produced when acetone (1 mol), potassium hydroxide (1 mol) and calcium carbide (1 mol) are suspended in ether for 24 hours at 0°C., with subsequent addition of water.[194] Oxidation of this carbinol by passing it over anhydrous magnesium sulphate at elevated temperature yields isopropenylacetylene, according to Favorskii.[195] Reaction of isopropenvlacetylene with hydrochloric acid, using cuprous chloride as catalyst, gives chloroisoprene.[196] By catalytic addition of hydrochloric acid to dimethylethinylcarbinol, dimethylchlorovinylcarbinol is formed.[197] Methyl β-chlorovinyl ketone results from reaction of acetylene with acetyl chloride at 15°C., using aluminum chloride as catalyst.[198] Schroeter[199] reports that crystalline acetaldehydedisulphonic acid is prepared by saturating fuming sulphuric acid with acetylene and allowing to stand for several weeks in the absence of moisture.

REACTIONS OF ACETYLENE HOMOLOGUES

Because of their relative difficulty of preparation, the homologues of acetylene have received only slight attention as compared with acetylene itself. One method of preparation is by the reaction of organic halides with sodium acetylide.[200] The latter is made by passing acetylene into a solution of metallic sodium in liquid ammonia until the blue color has disappeared. In this manner, methyl iodide and sodium acetylide yield methylacetylene (allylene). Likewise, methylacetylene added to sodium in liquid ammonia gives sodium methylacetylide, which in turn reacts with methyl iodide to form dimethylacetylene:

$$2CH_3C{\equiv}CH + 2Na \longrightarrow 2CH_3C{\equiv}CNa + CH_3CH{=}CH_2$$
$$CH_3C{\equiv}CNa + CH_3I \longrightarrow CH_3C{\equiv}CCH_3 + NaI$$

Calcium acetylide may be obtained either by passing acetylene into a solution of metallic calcium in liquid ammonia or by adding the latter solution to one of acetylene in liquid ammonia. The second method is the more rapid, according to Vaughn and Danehy.[201] These workers obtained pure 1-butyne in theoretical yield from diethyl sulphate and calcium acetylide in liquid ammonia. Amyl chloride, amyl bromide and butyl bromide likewise react with calcium acetylide to give amylacetylene and butylacetylene, respectively.

Another method of preparing alkylacetylenes is by dehydrohalogenation of certain organic halides by sodium[202] or sodamide[203] in liquid ammonia. With sodium, phenylacetylene was obtained in 96 per cent yield from β-bromostyrene and in 66 per cent yield from styrene dibromide. Also, by the same method p-methyl-α-chlorostyrene gave a 63 per cent yield of tolylacetylene. By employing sodamide, phenylacetylene may be procured from α-chlorostyrene, β-bromostyrene and styrene dibromide, butylacetylene from butyliodoacetylene, amylacetylene from 1,2-dibromoheptene, hexylacetylene from 2-bromo-1-octene and octylacetylene from 1,2-dibromodecane. The sodamide was prepared from sodium in liquid ammonia, using ferric nitrate as catalyst. Bachman and Hill[204] made 1-heptyne by dehalogenation of various bromo and chloro derivatives of heptane and heptene. Vapor-phase dehalogenation was effected with soda lime; liquid-phase with potassium hydroxide suspended in mineral oil. In Table 152 the boiling points of a number of allene and acetylene hydrocarbons are given.[205]

Although acetylene polymerizes to mono- and divinylacetylene in an acid solution of cuprous and ammonium salts,[206] some of the monosubstituted acetylenes do not act in an analogous way.[207] For instance, when phenylacetylene is heated in an acid solution of cuprous chloride and ammonium chloride, a yellow complex, $C_{16}H_{10}{\cdot}CuCl$, is formed, which is readily decomposed by ether to diphenylbiacetylene, $C_6H_5C{\equiv}CC{\equiv}CC_6H_5$.

The condensation of alkylacetylenes wtih methanol, employing a mercuric oxide-boron trifluoride catalyst,[208] yields ketals (2,2-dimethoxyalkanes). With acetic acid in place of methanol, α-alkylvinyl esters result.[209] In acid solution ketals are

C_4H_6	Methylallene	$CH_3CH=C=CH_2$	18
	Ethylacetylene	$CH_3—CH_2—C\equiv CH$	8.5
	Dimethylacetylene	$CH_3—C\equiv C—CH_3$	27-28
C_5H_8	*n*-Propylacetylene	$CH_3—CH_2—CH_2—C\equiv CH$	40
	Methylethylacetylene	$CH_3—CH_2—C\equiv C—CH_3$	55
	Isopropylacetylene	 $(CH_3)_2CH—C\equiv CH$	28
	Dimethylallene	$CH_3—CH=C=CH—CH_3$	41
C_4H_2	Diacetylene	$CH\equiv C—C\equiv CH$	9.5
C_4H_4	Vinylacetylene	$CH_2=CH—C\equiv CH$	5
C_5H_6	α-Methyl-β-vinylacetylene	$CH_2=CH—C\equiv C—CH_3$	59
	2-Methyl-vinylacetylene	 $CH_2=C(CH_3)—C\equiv CH$	33
C_6H_8	α-Ethyl-β-vinylacetylene	$CH_2=CH—C\equiv C—C_2H_5$	85
	2-Ethyl-vinylacetylene	 $CH_2=C(C_2H_5)—C\equiv CH$	66
C_6H_6	Dipropargyl	$CH\equiv C—CH_2—CH_2—C\equiv CH$	86
	Methylpropargylacetylene	$CH_3—C\equiv C—CH_2—C\equiv CH$	78-83
	Butadienylacetylene	$CH_2=CH—CH=CH—C\equiv CH$	84
	Divinylacetylene	$CH_2=CH—C\equiv C—CH=CH_2$	83-84
	Dimethyldiacetylene	$CH_2—C\equiv C—C\equiv C—CH_3$	129-130
C_8H_8	Vinylbutadienylacetylene	$CH_2=CH—C\equiv C—CH=CH—CH=CH_2$	43-45 (11 mm.)
C_8H_6	Divinyldiacetylene	$CH_2=CH—C\equiv C—C\equiv C—CH=CH_2$	33 (9 mm.)

quite unstable, hydrolyzing to methanol and the corresponding ketone. The mechanism of ketal formation is thought to be stepwise, the intermediate products being vinyl ethers. Reaction of monohydric alcohols (other than methanol) with alkylacetylenes, employing the above-mentioned catalyst, yielded polymeric products only, from which no ketals could be isolated. It was then found that with the addition of a small percentage of trichloroacetic acid to the catalyst, high yields of 2,2-dialkoxyalkanes were obtained from straight-chain monohydric alcohols and alkylacetylenes.[210] It is reported that under peroxide-free conditions methylacetylene adds hydrogen bromide to form 2,2-di-bromopropane, but in the presence of peroxides 1,2-bibromopropane results.[211] Similar experiments were conducted with butylacetylene.[212] In the absence of peroxides, the products were 2-bromo-1-hexene and 2,2-dibromohexane, but 1-bromo-1-hexene and 1,2-dibromohexane were found with peroxides present.[213]

Alkylacetylenes have been found to condense with polyhydric alcohols and

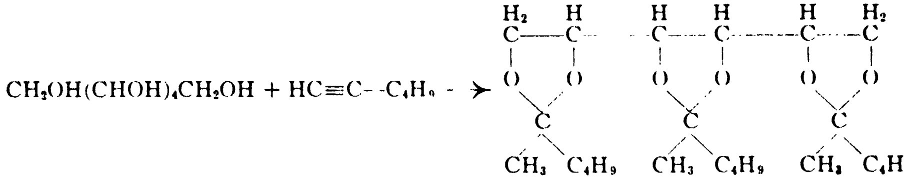
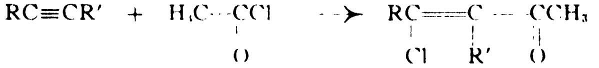
[213] For a discussion of the peroxide effect on addition of hydrogen bromide to acids having triple bonds, see P. L. Harris and J. C. Smith, *J.C.S.*, 1935, 1572; *Brit. Chem. Abs.* **A**, 1936, 53; *Chem. Abs.*, 1935, **29**, 7278.

α-hydroxy acids to form dioxolanes and dioxolones.[214] For example, with catalysts of mercuric oxide and boron trifluoride in methanol, mannitol and butylacetylene yielded 2-butyl-2-methyl-4,5-bis-(2-butyl-2-methyl-1,3-dioxolan-4-yl)-dioxolane (b.p., 210-212°C. at 9 mm.). This reaction is represented as follows:



The investigation of the reaction between acetyl chloride and alkylacetylenes has been carried out by Kroeger, Sowa and Nieuwland.[215] The main reaction involving the formation of chloro-olefinic ketones is represented as follows:



$$RC{\equiv}CR' + H_3C-\underset{O}{\overset{\|}{C}}Cl \longrightarrow R\underset{Cl}{C}=\underset{R'}{C}-\underset{O}{C}CH_3$$

These workers found stannic chloride, in 2 to 4 per cent concentrations, to be the most effective catalyst. The experiments of Ryden and Marvel[216] show that sulphur dioxide reacts with monosubstituted acetylenes to form polysulphones, whereas the disubstituted derivatives do not add in this manner.

Primary acetylenic alcohols of the type $RC{\equiv}CCH_2OH$ may be prepared by the action of formaldehyde vapor on the Grignard derivatives of the corresponding alkylacetylenes.[217] Reaction of acetylene with alkyl mercury bromides yields the corresponding bis-(alkylmercury) acetylides.[218]

Grignard reagents enter several other reactions involving acetylenes.[219] For example, allyl bromide reacts with *n*-butylacetylenemagnesium bromide in the presence of anhydrous cuprous chloride to yield *n*-butylallylacetylene (b.p., 58°C. at 22 mm.). This may be represented as follows:

$$C_4H_9-C{\equiv}C-MgBr + H_2C{=}CH-CH_2Br \longrightarrow C_4H_9-C{\equiv}C-CH_2-CH{=}CH_2$$

The addition of alkyl sulphates to acetylenic Grignard reagents has been described by Thorn, Hennion and Nieuwland.[220] Using metal halides, Danehy and Nieuwland[221] prepared diacetylenes, such as diphenyldiacetylene from cupric bromide and phenylacetylene magnesium bromide.

The isolation of the hydrogen isotope, deuterium,[222] and the possibility of obtaining significant quantities of heavy water (deuteriowater) as a source of deuterium[223] have led to some investigation of the synthesis and properties of deuterioacetylene. One method of preparation is by the action of heavy water on calcium carbide. Clemo and McQuillen[224] state that the action of 99 per cent heavy water on calcium carbide results in a 60 per cent yield of deuterioacetylene. The latter compound is made also by isotopic exchange between acetylene and heavy water.[225]

It has been noted that deuterioacetylene, under the influence of x-rays, undergoes polymerization at about the same rate as ordinary acetylene.[226] Clemo and McQuillen[227] reported that deuterioacetylene under controlled conditions may be polymerized to hexadeuteriobenzene. Deuterioacetaldehyde has been prepared by the hydration of deuterioacetylene in an acid solution of mercury salts in heavy water.[228]

Chapter 29

Halogenation of Methane. Properties and Uses of Halogen Derivatives

Methods of chlorination of methane may be conveniently subdivided into three main divisions, viz.: thermal, catalytic and photochemical.[1] In all of these methods it is essential that temperature control be rigorously maintained, otherwise reaction between methane and chlorine may proceed with formation of carbon and hydrogen chloride, often with explosive violence. In purely thermal operations temperatures of 250-300°C. are generally employed, though with short times of contact as high as 1400°C. has been recommended. Inert diluents, such as nitrogen, are helpful in controlling the rate of reaction. Many types of catalysts have been suggested, as for example, antimony pentachloride, ferrous or ferric chloride, partially reduced cupric chloride, activated carbon and pumice. Combination of methane and chlorine is accelerated also by light radiation, such as sunlight, actinic rays, light from a carbon arc, metallic filament, or mercury vapor lamp. The advantage of photochemical chlorination appears to be that it can be effected at room temperature or lower. However, in most instances careful control of illumination is necessary to prevent the reaction from getting out of hand.

In all cases the products consist of a mixture of chlorinated hydrocarbons, though by selecting proper conditions a preponderance of one chloro-methane may be obtained. Thus, Giordani[2] reports that methane and chlorine, in the ratio of 9:1, conducted over a catalyst at 450°C. furnished an 89 per cent yield of methyl chloride. The contact agent was partially reduced cupric chloride containing 1 per cent of cerium chloride. Dilution of the reactants with hydrogen chloride and use of higher temperatures yields mainly carbon tetrachloride. In this manner Kiprianov and Kusner[3] secured a 90 per cent yield of the tetrachloride by passage of methane, chlorine and hydrogen chloride (16:64:[80-100] liters) over activated carbon at 525-530°C. Tomasik[4] recommends employing air in place of chlorine. For example, 70 per cent of the chlorine in a gaseous mixture of methane, hydrogen chloride and air (2:9:18) was converted, at 400°C. in the presence of cupric chloride, into chlorinated products. Of the latter 90 per cent was carbon tetrachloride.

PROPERTIES AND USES OF CHLOROETHANES

Methyl chloride, CH_3Cl, is a colorless gas possessing a characteristic odor and burning with a white flame. It can be condensed to a liquid boiling at —24°C.

---

at 760 mm. Its critical temperature and pressure are 143.1°C. and 65.8 atmospheres, respectively. This chloromethane may be employed as a refrigerant, particularly when dissolved in a solvent such as a mixture of α- and β-chloronaphthalenes[5] or β,β'-dichloroethyl ether,[6] and (under pressure) as a diluent in the dewaxing of mineral oils.[7] Stabilization, or prevention of development of acidity, of liquid methyl chloride is accomplished by incorporation of a small proportion (0.001 to 1 per cent) of phenolic substances, such as phenol, resorcinol, *p*-cresol, or α-naphthol.[8]

Hydrolysis of this chloride with steam at 400°C. furnished 16 per cent methyl alcohol and a like percentage of formaldehyde.[9] The ratio of chloride to steam should be 1:10 and the yields can be increased by recycling the residual gases. Tin phosphate on pumice was a satisfactory catalyst, but titanium dioxide or a mixture of tin and iron phosphates proved unsatisfactory. Also, it has been reported that methyl chloride may be condensed with aldehydes to produce saturated hydrocarbons.[10] Thus, the above halide was heated with formaldehyde to 350°C. A small proportion of cupric oxide was incorporated in the reaction zone to aid in the condensation. The interaction of methyl chloride and carbon monoxide has been utilized in the production of acetyl chloride.[10a] In the procedure, the two reactants, at a temperature of 860°C., are led over a copper catalyst for a period of 0.3 second.

By progressive chlorination of chloromethane there are obtained methylene chloride, chloroform and carbon tetrachloride.[11] Mixed with one-third its volume of chlorine and heated to 360-380°C., methyl chloride gives principally methylene chloride.[12] On the other hand when a larger proportion (46 per cent by volume) of chlorine and temperatures of 400° to 650°C. are employed, followed by further addition of the halogen (85 per cent by volume of the halides present) and reheating, both methylene chloride and chloroform are secured.[13] Levine[14] recommends using a mixture of methyl chloride, ethylene chloride and chlorine (in the volume-ratio of 2:2:1 to 4:3:1) and temperatures of 400° to 500°C. When chlorination is complete the gases are cooled to 200°C., 1 to 1.5 volumes of chlorine added and the reactants again subjected to the higher temperatures. This procedure results in a 15 to 30 per cent yield of chloroform.

Dichloromethane, (*methylene chloride*), CH_2Cl_2, is a colorless liquid (*d.* 1.337) having a chloroform-like odor. Its vapor, or saturation, pressure over the range of −20° to +16°C. may be represented by the formula

$$\log_e p_s = 17.89600 - (4.1191 \times 10^3/T) + (3.573 \times 10^6/T^2) - (5.386 \times 10^7/T^3)$$

in which p_s is the saturation pressure in mm. of mercury, and T is the temperature in degrees absolute.[15] Calculations, according to this formula, indicated its boiling point to be 40.18°C., critical temperature 216°C., and critical pressure 49.7 kg. per sq. cm. At 460°C., in the presence of a large excess of steam and tin phosphate on pumice (as a catalyst), it is hydrolyzed to give a 75 per cent yield of formaldehyde.[16] When mixed with methyl chloride and the mixture hydrolyzed under the same conditions, methylene chloride reacts to the extent of 90 per cent while only 30 per cent of the methyl chloride is affected. Also, it has been pointed out that the dichloride may be condensed with formaldehyde to furnish chloroacetaldehyde.[17] The reaction was effected at 300°C. in the presence of sulphuryl chloride, which served as a promoter.

Admixed with other solvents (e.g., naphtha or butyl alcohol) this dichloromethane has been suggested as a dewaxing agent for lubricating oils.[18] It may be employed also as a constituent of compositions for the preparation of films from acetylcellulose,[19] and for cleaning paints, varnishes or enamels.[20] When mixed with benzene it furnishes a composite solvent applicable for extraction of lecithin and fat from corn or soy beans.[21] Collier[22] points out that methylene chloride can be used with safety only when ventilation is adequate. Development of acidity and corrosion of metals by this dichloride are inhibited by incorporation of 0.5 to 2 per cent of an unsaturated hydroaromatic compound, e.g., pinene.[23]

Chloroform, $CHCl_3$, because of its well-known applications as an anesthetic,[24] solvent and extraction agent, is an important chlorinated derivative of methane. It is also miscible with many organic liquids. Bottecchia[25] reports that when mixed with nitrobenzene maximum contraction occurs with 50 per cent (by weight) of chloroform at −16°C. or with 65 per cent at 40°C. The greatest expansion (between 16° and 40°C.) of chloroform-benzene mixtures is obtained with one containing 27 per cent (by weight) of the chloro-hydrocarbon.[26] When mixed with butane and ethyl ether, chloroform is reported to furnish an effective dielectric for electric cables.[27] Zappi and Degiorgi[28] believe that the hydrogen (in chloroform) is in an active state, and that the structure of this chloro-derivative may be represented by the coordination formula $(CCl_3)H$. On the other hand, the hydrogens in bromoform and iodoform are, respectively, 50 and 3 per cent active, thus indicating a mixture of coordinated and normal structures.

According to Rozeboom,[29] chloroform may be distinguished from carbon tetrachloride in the following manner. A small crystal of iodine is dissolved in the liquid and then a few milligrams of papaverine hydrochloride added. If the solvent is carbon tetrachloride no reaction occurs, otherwise the alkaloid salt dissolves and the violet color of the solution is changed to a yellowish red. Another test comprises the reduction of boiling Fehling's solution with chloroform.[30] Also, when a drop of carbon tetrachloride is heated in a loosely corked test tube (flameless combustion) it is converted into phosgene and chlorine, and the latter detected by potassium iodide and starch. Madsen[31] has developed a method for showing the presence of carbon tetrachloride in chloroform. Twenty grams of the liquid are carefully evaporated until 0.5 cc. remains. This is shaken with 150 times its weight of water. A distinct opalescence indicates 1 per cent of the tetrachloride; if none of the latter is present, complete dissolution occurs in 2 minutes.

Fractionation of primary tars with chloroform furnishes neutral oils, resinous bodies and phenols.[32] Danaila and Soare[33] report that the only method, which is technically and economically advantageous, for making chloropicrin is the nitration of trichloromethane. They obtained a 58 per cent yield by heating equal volumes of chloroform and nitric acid (*d.* 1.52) at 140-150°C. for 2 hours under pressure. The action of Friedel-Crafts condensing agents upon chloroform has been investigated.[34] It was stated that the trichloride will react with *p*-dichlorobenzene in the presence of aluminum chloride. When solvents are excluded from the reaction zone and the temperature maintained at 20°C. the product is said to be tri-(2,5-dichlorophenyl) methane. When admixed with dimethyl ether and conducted over alumina gel at 280°C., chloroform is said to furnish methyl chloride.[34a]

The preparation of chloroform-d (deuteriochloroform) from chloral deuterate and sodium deutroxide is described by Breuer.[35] Also, it has been suggested that chloral (trichloroacetaldehyde) be treated with calcium oxide and deuterium oxide (heavy water) to furnish heavy chloroform.[36] At 732 mm. this trichloro compound boiled 0.5°C. higher than its lighter analogue. Some of the other physical properties of these two trichloro derivatives are given in Table 153.

Carbon tetrachloride, CCl_4, is a heavy, colorless liquid (sp. gr. 1.595) boiling at 76.7°C. at 760 mm. As previously mentioned it can be prepared by chlorination of methane. Another method consists in saturating carbon disulphide with chlorine and warming the mixture to 40-60°C.[37] Catalysts such as iron, manganese, chromium or silicon may be used. A 68-80 per cent yield is reported to be obtained by passage of sulphur dichloride over carbon at 1000°C.[38] Weiler[39] reports that the volatile reaction products from the exhaustive chlorination of coal for 6 days at 200°C. consisted of carbon tetrachloride, hexachloroethane and hexachlorobenzene. According to Davies[40] the dielectric constants for the tetrachloride at 20°C. and 25°C. are 2.236 and 2.227, respectively. He recommends it as a secondary standard for calibrations. The crystalline forms of both the tetrachloride and tetrabromide are bimolecular while those for ethylene chloride or bromide are tetramolecular.[41]

FIG. 154.—Apparatus for Quantitative Determination of Carbon Tetrachloride Vapor. (J. C. Olsen, H. F. Smyth, Jr., G. E. Ferguson and L. Scheflan)

Carbon tetrachloride and other chlorinated hydrocarbons, particularly when moist, slowly undergo decomposition in contact with metals such as iron, zinc, copper or Monel metal. Numerous agents have been suggested as stabilizers or inhibitors of such action and include mercaptans,[42] e.g., butyl mercaptan, ethyl acetate,[43] natural resins,[44] such as gum mastic or rosin, alkyl or aryl cyanamides,[45] thiocarbamides,[46] ureides,[46a] hexamethylenetetramine[47] and ethyl cyanide.[48]

The tendency of carbon tetrachloride to undergo decomposition when mixed with moist air has been made the basis of a quantitative method of determining the tetrachloride.[49] The apparatus consists of a glass funnel connected to an electric furnace through a silica tube. At the outlet of the latter are placed a series of absorption bottles containing aqueous caustic soda and an aspiration bottle (see Fig. 154). In the procedure a weighed amount of carbon tetrachloride is placed in the funnel. The furnace is then heated to 1000-1100°C. and a mixture of vaporized carbon tetrachloride and moist air drawn through, forming hydrogen chloride and carbon dioxide.

$$CCl_4 + 2H_2O \longrightarrow CO_2 + 4HCl$$

To insure the presence of a sufficient quantity of water a small porcelain boat containing water is placed at the entrance to the furnace. As the gases leave the furnace, the hydrogen chloride is absorbed in a known volume of the aqueous caustic soda. The excess hydrochloric acid may then be determined by titration of these solutions with silver nitrate.

Uses suggested for carbon tetrachloride are, as a dewaxing[50] and refining agent,[51] either alone or blended with other halogenated hydrocarbons; in the processing of lubricating oils; as a decarbonizing reagent for internal combustion engines;[52] in the preparation of sand molds;[52a] as a cleaning agent for metals;[52b] in the preparation of cosmetics;[53] and mixed with wax-like ketones in the manufacture of waxing and polishing compositions for automobiles, furniture and floors.[54] A die lubricant, to be employed in the extrusion of magnesium alloys, is made by suspending finely-ground graphite in the tetrachloride.[55] The production of chloral is said to be effected by the interaction of carbon tetrachloride and formaldehyde.[56] The condensation may be carried out at temperatures in the range 200-500°C. and at pressures from 20 to 200 atmospheres. Passage of the vapors of tetrachloromethane through granular carbon at 600-1500°C. (best at 800-900°C.) furnishes tetra- and hexachloroethane.[57] These may be separated by fractional distillation, or the mixture subjected to chlorination to increase the yield of the hexachloro compound. Also, a phthalyl chloride is stated to be furnished by admixing phthalic anhydride and carbon tetrachloride and heating the resulting composite to 250-280°C.[58] A resin applicable in molding is reported to be formed by the reaction of petrolatum with carbon tetrachloride in the presence of aluminum chloride.[58a] In one example 100 g. of petrolatum were admixed with a like amount of anhydrous aluminum chloride and heated to 80°C. Carbon tetrachloride (100 g.) was then incorporated and the mass heated until all gaseous products were evolved. In this manner 94 g. of a resin which contained 3 to 13 per cent of chlorine was said to be formed.

Because of its non-inflammable properties tetrachloromethane has found application in the preparation of insecticidal sprays, dry-cleaning compositions and fire-extinguishers. A spray for use as an insecticide in airplanes consists of 1 part of pyrethrum extract in kerosene and 4 parts of carbon tetrachloride.[59] Badertscher[60] suggests suspending talc in such preparations, so that after spraying plants the latter become coated with a fine insecticidal dust.

Dry-cleaning liquids may comprise the tetrachloride incorporated with another halogenated hydrocarbon such as ethylene chloride,[61] or blends of petroleum naphtha with sufficient carbon tetrachloride or acetylene tetrachloride,[62] or mixtures of these chlorides,[63] to render the composition non-flammable. The addition of a small proportion of an oil-soluble alkali sulphonate, called mahogany soap, to a petroleum naphtha-carbon tetrachloride blend has been suggested to increase the detergent properties of the cleaning fluid.[64] To eliminate fire and explosion hazards connected with the handling of hexane, heptane, octane, gasoline and naphtha, Jones and Kennedy[65] recommend incorporation of at least 70 per cent by volume of tetrachloride. With pentane 80 per cent is required. Although recovery of dry-cleaning solvent by distillation is the usual practice, Stout and Tillman[66] point out that continuous adsorption and filtration processes have certain advantages as for instance reduction in cost and time required for reclamation. They state that it is necessary to remove saponifiable materials and acids, but that the presence of mineral oils (in moderate concentrations) in the fluids is helpful in cleaning operations. With an azeotropic mixture of carbon tetrachloride and ethylene chloride, it was found that activated carbon and magnesium oxide removed saponifiable oils and acids, and that silica gel eliminated both saponifiable and unsaponifiable substances.

The use of carbon tetrachloride, either alone or incorporated with other halogenated hydrocarbons, in fire-extinguishers is well-known.[67] The development of phosgene during the application of this liquid to fires has been measured by Yant,

Olsen, Storch, Littlefield and Scheflan.[68] These investigators observed that in the case of fires with excelsior (as the inflammable material) 4 to 92 parts per million (by volume) of phosgene were formed, an average value being about 23.6 parts per million. However, when carbon tetrachloride was dropped onto a red-hot iron beam the proportion of phosgene rose to 119 parts per million. Malzac[69] suggests that the fire-extinguishing liquid may be stabilized and the formation of carbonyl chloride and hydrogen chloride prevented by incorporation of aniline. The mechanism of the extinguishing power of carbon tetrachloride on coal-gas flames was investigated by Dufraisse and LeBas.[70] They believe the action to be complex, a combination of dilution of the surrounding atmosphere and consequent cooling, a definite antioxygenic influence, and a combustion-supporting effect due to hydrogen (of the combustible material) reacting with the chlorine in preference to oxygen.

The toxic properties of carbon tetrachloride have been studied by Lehnherr,[71] Ciaravino,[72] Löwy,[73] Young,[73a] and Maiofis, Shusterovich and Bibikov.[74] According to Okunevskii[75] the efficiency of insecticides depends upon the lethal concentration of the toxic material and the rate at which it is capable of producing that concentration. Liquids which are particularly applicable for this purpose are carbon tetrachloride and benzene, since they are sufficiently volatile at ordinary temperatures. The use of this tetrachloride as a parasiticide was investigated by Ackert and Graham.[76].

PREPARATION OF CHLOROFLUOROMETHANES

These mixed halogenated hydrocarbons, particularly dichlorodifluoromethane, are usually prepared by the action of antimony trifluoride on carbon tetrachloride, using antimony pentachloride as a catalyst.[77] The reaction is represented as

$$3CCl_4 + 2SbF_3 \xrightarrow{SbCl} 3CCl_2F_2 + 2SbCl_3$$

McNary[78] points out that the presence of a small proportion of antimony dichlorotrifluoride increases the speed and the efficiency of the reaction. This latter compound can be obtained by the interaction of chlorine with the metallic fluoride at temperatures above 70°C. Lead or zinc fluoride may be employed in a similar manner. Another procedure for effecting fluorination comprises treatment of the chloro-hydrocarbon, carbon tetrachloride or tetrachloroethane[79] with antimony trifluoride and simultaneously introducing chlorine into the reaction zone. In the procedure carbon tetrachloride was pumped to a reaction chamber containing antimony trifluoride. At the same time chlorine was introduced into the chamber. The latter was heated by passage of steam through a jacket which surrounded it. During the time of interaction the temperature was maintained at 60-65°F. and the pressure at 55 pounds gage (69.7 pounds per sq. in.). The gaseous products, including dichlorodifluoromethane, trichlorofluoromethane and unreacted carbon tetrachloride were then led to a dephlegmator, where the trichloro and tetrachloro compounds were condensed and returned to the fluorinating chamber, while difluorodichloromethane was washed with aqueous caustic soda, dried with concentrated sulphuric acid, and condensed. Also, it has been suggested that methylene chloride be reacted with antimony trifluoride.[80] In this instance antimony pentachloride rather than chlorine was incorporated in the reaction zone. When the temperature was maintained at 80°F. and the pressure at 130 pounds gage (144.7 pounds per sq. in.) difluoromethane was stated to be the main product. The di-

In place of the above-mentioned metallic fluorides, hydrogen fluoride (mixed with a hydrogen halide) may be employed as the fluorinating agent and activated carbon as the catalyst.[81] When operations are carried out in the vapor phase at slightly elevated temperatures (110-170°C.) in the absence of contact materials, aralkyl halides are converted into fluorides.[82] An example of this is the preparation of benzotrifluoride from the corresponding trichloride. The latter procedure is applicable also to the transformation of trifluorotrichloroethane into pentafluorochloroethane.[83] However, other catalysts which may be used with hydrogen fluoride (and chloromethanes) include antimony tri- and pentachloride,[84] antimony

fluorochlorides,[85] a mixture of phosphorus pentachloride and antimony pentachloride,[86] and ferric chloride.[87] For example, carbon tetrachloride, antimony trifluoride and antimony pentachloride may be admixed in a reaction vessel at atmospheric pressure. The gaseous products are then conducted to a dephlegmator which is cooled by a refrigerant to —20°C. In this manner all partially fluorinated and unreacted hydrocarbons are condensed and returned to the fluorinating chamber. The dichlorodifluoromethane is led from the top of the dephlegmator, washed and compressed. Silicon tetrafluoride[88] and bromine trifluoride[89] have also been proposed as fluorinating agents.

sulphate) may be incorporated with the calcium compound.[91] Slow passage of chloroform vapors over mixed calcium and silver fluorides at 100°C. yielded about 57 per cent of monofluorodichloromethane.[92] At 250°C. approximately 48 per cent of difluoromonochloromethane is obtained, and at 340°C. only 10 per cent of fluoroform is secured. Lead fluoride at 500°C. gave only a small proportion of monofluorodichloromethane. Croco[93] observed that treatment of fluorotrichloromethane with aluminum chloride (at 45°C.) yielded difluorodichloromethane and carbon tetrachloride. Similarly, fluorodichloromethane furnished difluoromonochloromethane.

It is interesting to note that trichlorofluoromethane and dichlorodifluoromethane may be prepared from carbon disulphide.[94] Thus, the latter substance was combined with hydrogen fluoride in the presence of antimony pentachloride and free chlorine. The resulting compound was said to contain a mixture of the two fluorine derivatives mentioned above.

Acidic impurities may be eliminated from fluorochloro derivatives by the action of an amine, such as aniline or triethanolamine.[95] The refined product afterwards is separated by fractional distillation.

Iodoform, mercurous fluoride and calcium fluoride (in the proportions of 20 : 33.4 : 40) heated to 80-150°C. yielded a mixture of fluoroform, iododifluoro- and di-iodofluoromethane which could be separated by distillation.[96] The di- and trifluoro derivatives were gases at room temperature while the monofluoride was a liquid. Some of the physical constants of these compounds are given in Table 154.

TABLE 154.—*Physical Constants of the Fluorine Derivatives of Iodoform.*

Compound	B.P.	M.P.	*d* (at liquid air temperature)
CHI_2F	100.3°C.	−34.5°C.	3.604
$CHIF_2$	21.6°C.	−122.0°C.	3.238
CHF_3	−84.4°C.	−160.0°C.	1.935

Fluoroform appeared to be the most stable as it was not decomposed on heating to 1150°C. It was not attacked by nitric acid (alone or mixed with sulphuric acid), nitrogen trioxide, or silver nitrate at 150°C. for 14 hours. At temperatures above 175°C. fluoroform was decomposed by the trioxide. When affected by oxidizing agents it was changed into carbonyl fluoride and hydrogen fluoride. Iododifluoromethane was very sensitive to light and air, reacted with silver nitrate and was decomposed by platinized asbestos at 700°C. Diiodofluoromethane also was sensitive to light and air, slowly liberated iodine when warmed, and was almost completely decomposed at 250°C. The diiodo compound yielded ammonium iodide and fluoride on treatment with ammonia. With sodium sulphite in 50 per cent alcohol complete removal of fluorine was observed.

USES OF CHLOROFLUOROMETHANES

Because of their relatively low boiling points, non-flammability and low toxicity these halogenated methanes, especially dichlorodifluoromethane,[97] have been employed as refrigerants. A diester, such as dibutyl phthalate, may be used in conjunction with them as the absorbent.[98] Also, a number of ethers and esters of glycol may be incorporated for the same purpose.[99] Incorporation of a small proportion of a substance which fumes in contact with moisture in the atmosphere (e.g., boron trifluoride, silicon tetrachloride or titanium tetrachloride) serves to detect leaks in the refrigerating system.[100] Another method of detecting leaks in refrigeration machines which contain dichlorodifluoromethane consists of passing

Chapter 30

Halogenation of Methane Homologues. Properties and Uses of Halogen Derivatives

As the number of carbon atoms in the members of the paraffin series becomes greater, the number of possible halogen-substituted derivatives increases enormously,[1] and efforts to control chlorination and thus obtain a preponderance of one halogen derivative to the exclusion of others become a matter of importance.

Hass, McBee and Weber[2] have given the following general rules for chlorination of the saturated hydrocarbons:

1. Carbon skeleton rearrangements do not occur during photochemical or thermal chlorination if pyrolysis temperatures are avoided; every possible monochloride is always formed.
2. At low temperatures the secondary and tertiary hydrogen atoms are substituted more quickly than are the primary.
3. At increasing temperatures the rates of substitution approach equality in the liquid and vapor phase.
4. Liquid phase chlorination gives relative rates of primary, secondary and tertiary substitution which are obtainable only at much higher temperatures in the vapor phase.
5. The presence or absence of moisture, carbon surfaces or light has no appreciable effect upon the rate of substitution.
6. Excessive temperatures or reaction times cause pyrolysis of the tertiary, secondary and primary chlorides in that order.
7. If a molar excess of hydrocarbon is used and the chlorinating conditions are maintained constant, the yield of monochlorides vs. polychlorides may be calculated from the equation:

$$X = KY$$

where X = weight ratio of monochlorides over polychlorides, Y = ratio of moles of hydrocarbon over moles of chlorine, and K = a constant peculiar to the hydrocarbon and the conditions.

---

[1] H. P. Henze and C. M. Blair (*J.A.C.S.*, 1934, **56**, 157; *Brit. Chem. Abs.* **A**, 1934, 276; *Chem. Abs.*, 1934, **28**, 1656.) have calculated the number of disubstituted products of the paraffin series. Some of their values are as follows:

No. of Carbon Atoms	No. of Di-chlorides	No. of Carbon Atoms	No. of Di-chlorides
1	2	7	339
2	4	8	887
3	9	9	2,338
4	21	10	6,220
5	52	15	888,467
6	132	20	135,567,103

For a discussion of the number of mono-substitution products see Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., Inc., New York, 1934.

[2] H. B. Hass, E. T. McBee and P. Weber, *Ind. Eng. Chem.*, 1935, **27**, 1190; 1936, **28**, 333; *Chem. Abs.*, 1936, **30**, 78, 2913; *Brit. Chem. Abs.* **B**, 1935, 1084; **A**, 1936, 587; *J. Inst. Pet. Tech.*, 1935, **21**, 449A; 1936, **22**, 202A.

8. Dichlorination proceeds by two mechanisms: (1) loss of hydrogen chloride followed by addition of chlorine to the resulting olefin and (2) progressive substitution.

9. In vapor phase chlorination the presence of a chlorine atom on a carbon atom tends to hinder further reaction upon that carbon atom during the second substitution.

CHLORINATION OF ETHANE

In general the chlorination of ethane can be accomplished by three methods, thermal, catalytic and photochemical.[3] Temperatures from 300-500°C. are employed with 1 volume of chlorine and 8 volumes of ethane, both in the gaseous phase. If the reaction is carried out in the dark the temperature range may be limited to 360-380°C. Contact agents such as iron, thallium, alkaline-earth chlorides, charcoal and pumice impregnated with cupric chloride, which promote chlorination, are also used. Exposure to diffused daylight at 5°C., to ultraviolet rays at 80-100°C. and to the light from a mercury vapor lamp have been recommended. In the latter method ethyl chloride is not the only product; di-, tri-, tetra,- penta-, and hexachloroethane are also present, together with some ethylidine chloride.

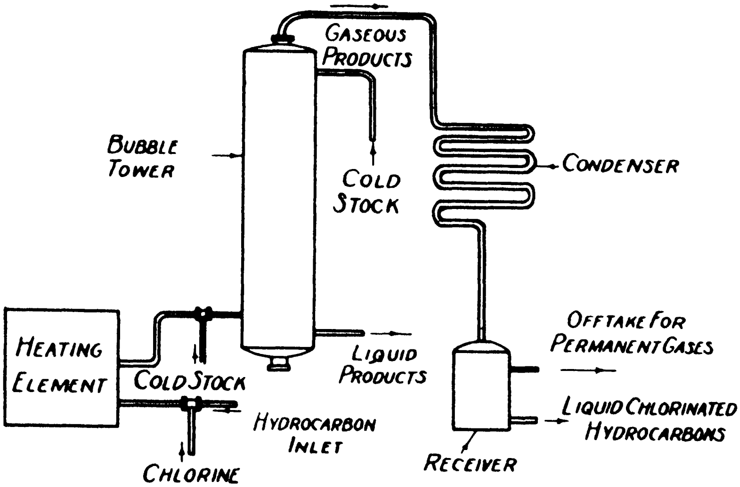

FIG. 158.—Sketch of Method for Chlorination of Gaseous Hydrocarbons. (G. Egloff)

The chlorination of still gases to secure ethyl chloride is reported by Egloff.[4] He passed a mixture of chlorine and gaseous hydrocarbons through a reaction zone which was heated to 250-750°F. The temperature of the exit gases was lowered quickly by the injection of a cooling medium consisting of some of the unreacted gases, the purpose being to prevent formation of carbon and hydrogen chloride. The products were then conducted through a bubble tower to which some fresh cold gases were added. The liquid chlorides and non-condensed materials were separated, the former being removed from the bottom of the tower. To effect chlorination in liquid phase, a solvent such as carbon tetrachloride or benzene for the above reactants has been recommended.[5]

---

[3] See Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., Inc., New York, **1934**. For a review of the photochemical reactions between halogens and aliphatic hydrocarbons, see H. J. Schumacher, *Angew. Chem.*, 1936, **49**, 613; *Chem. Abs.*, 1936, **30**, 7041.

The preparation of alkyl polyhalides is often effected by halogenation of alkyl mono- or dichlorides. According to Hamai,[6] ethylene chloride (dichloroethane) and chlorine do not combine at 25-50°C., but if a trace of hydrogen chloride is added, trichloroethane is formed. The reaction is preceded by an induction period. To obtain hexachloroethane, Levine and Bond[7] treat perchloroethylene (C_2Cl_4) with chlorine using a contact agent of pumice impregnated with cupric chloride and excluding light.

Fig. 159.—Apparatus Employed for Formation of *sym*-Dideuteriotetrachloroethane. (F. W. Breuer)

Other means of preparing ethyl chloride include the treatment of ethyl alcohol with hydrogen chloride, both in the liquid[8] and vapor[9] phases. Also, it has been suggested that gaseous ethylene be reacted with chlorine vapor to secure dichloroethane.[10] The two gases are conducted together over a promoter consisting of a mixture of zinc and stannous chlorides.

The formation of a tetrachloroethane containing two atoms of deuterium (*sym*-dideuteriotetrachloroethane) has been investigated.[11] The halogen compound was prepared by uniting heavy acetylene (dideuterioacetylene) with chlorine. The apparatus consisted of an acetylene-generating flask, a storage system of four bulbs to hold the acetylene, and two reaction chambers of heavy-walled tubing joined to receiving flasks (see Fig. 159). A chlorine-purifying train was connected to the reaction chamber at the same point that the heavy acetylene entered. The rate of acetylene was maintained constant by employing mercury as a confining liquid in the storage flasks. In the procedure a catalyst consisting of ferric oxide, reduced iron, aluminum oxide, powdered antimony and sand was employed. The heavy acetylene was generated by allowing deuterium oxide (heavy water) to fall upon calcium carbide. The chlorination was then effected by conducting chlorine at the rate of 16 cc. per minute and acetylene at 4 cc. per minute into the reaction chamber. The latter was heated by a 100 watt incandescent lamp at a distance of 40 cm. A yield of 78 per cent of the theoretical amount of *sym*-dideuteriotetrachloroethane was reported to be obtained.

PROPERTIES OF CHLORINATED ETHANE

The work of van der Lee[12] indicates that over the range 62.1 to 239.1°C. the vapor pressure of hexachloroethane is inversely proportional to the temperature and may be represented by the equations:

$$\log_{10} p = \frac{-2636.1}{T} + 8.640 \text{ for the liquid and}$$

$$\log_{10} p = \frac{-2103.6}{T} + 7.483 \text{ for the solid}$$

where p = vapor pressure and T = absolute temperature. The same investigator found the triple point[13] to be 186.8°C. and calculated the heats of sublimation, vaporization and fusion as 12.0, 9.6 and 2.4 kilogram calories per mole, respectively. The same figure for the triple point was obtained by Wiebenga.[14]

To stabilize tetrachloroethane and to prevent development of an objectionable degree of acidity a number of agents have been suggested. They include phenolic substances[15] (hydroquinone, p-cresol, resorcinol), propanol,[16] a mixture of a free fatty acid and soap,[17] butyl oxide,[18] and small proportions (0.05 per cent) of caffeine.[19] To determine the applicability of stabilizers, Dietrich and Lohrengel[20] treat the chlorinated hydrocarbon (both with and without incorporation of stabilizers) with oxygen at 25 atmospheres and 100°C. for 4 hours in the presence of water. The quantity of hydrogen chloride liberated is afterwards ascertained. Water prevents the formation of any appreciable proportion of phosgene by hydration of the chloride.

A proposed method for the quantitative determination of gaseous dichloroethane and ethyl chloride has been reported.[21] It is based upon the oxidation of the halides to form carbon dioxide, water and chlorine.

$$C_2H_4Cl_2 + 3O_2 \longrightarrow 2CO_2 + 2H_2O + Cl_2$$

The latter may then be absorbed in an appropriate reagent. The apparatus consisted of two electrically heated furnaces containing a quartz tube which was connected at one end to the incoming vapors and at the other to absorption bottles (see Fig. 160). A gas meter was employed to measure the rate of flow, which was controlled by a suction pump. The absorption bottles contained sodium arsenate to remove the chlorine. The gases under investigation were drawn through the combustion furnaces at the rate of 20 liters per hour. During the period of contact the furnace was maintained at temperatures in the range 900-950°C. When the combustion was completed, the apparatus was blown with air to remove all chlorine, and the amount of the latter held in the absorption liquid was determined. It was stated that the estimation of dichloroethane was accurate within 0.04 per cent by volume. However, it was said that the ethyl chloride determinations had an accuracy of ±10 per cent if 2 per cent or more of ethyl chloride was present.

USES OF CHLORINATED ETHANES

The chlorides of ethane have many varied applications, being employed in the preparation and purification of organic compounds, in refining and dewaxing lubricating oils, as refrigerants, in the manufacture of insecticidal compositions and as dry cleaning agents.[22]

---

[21] M. I. Dement'eva and E. K. Serebryakova, *Materials on Cracking and Chemical Treatment of Products Obtained, Khimteoret (Leningrad)*, 1935, No. 2, 146; *Chem. Abs.*, 1935, 29, 6033; *Brit. Chem. Abs.* B, 1936, 625. The apparatus employed is described by M. J. Martinek and W. C. Marti, *Ind. Eng. Chem., Anal. Ed.*, 1931, 3, 408; *Chem. Abs.*, 1931, 25, 5875.

Monochloroethane. To secure ethylated cellulose, Nikitin and Rudneva[23] recommend cellulose and ethyl chloride. They report that a temperature of 100-120°C. causes complete reaction in 5 hours and that a large excess of concentrated sodium hydroxide favors the production of a highly ethylated compound. The suggestion has been made that this chloroethane be used in a refrigerant mixture. For this purpose methylene chloride and monochloroethane are said to possess the advantage, according to Davenport,[24] that at room temperature (20°C.) they have a vapor pressure of less than 1 atmosphere. The two latter halides are also used as solvents for insecticidal compositions.[25]

Dichloroethane. Reilly[26] reports that when chlorine (containing 20 per cent of air) and dichloroethane are separately preheated to 120-180°C. and passed over coke at 375°C. they yield tetrachloroethylene. Dichloroethane may be employed as a solvent for crude naphthalene when the latter is refined with sulphuric acid[27] and as an extractant for sulphur in gas-purification residues.[28] Ethylidene chloride mixed with kerosene or benzene may be used as a dehydrating agent for aliphatic acids, such as acetic, and for the acid-anhydride product of thermal decomposition of these acids.[29] Ethylene chloride, alone[30] or incorporated with benzene,[31] isopropyl ether or amyl alcohol,[32] is a dewaxing agent for lubricating oils. In one dry cleaning process, a mixture of 75 per cent of dichloroethane and 25 per cent of trichloroethylene may be employed.[33] MacLang[34] effects selective extraction of caffeine with dichloroethane. The coffee is heated with water until a 16 per cent moisture content is attained, then the pressure is raised to 5 atmospheres and the temperature to 125°C. At the end of 30 minutes preheated dichloroethane is introduced and extraction brought about. The caffeine content of the coffee is lowered to 0.08 per cent by this means. It is also interesting to note that when incorporated with paraffin wax and resin the halide is reported to furnish a scouring agent for painted and waxed surfaces.[35]

Higher Chloroethanes. *unsym*-Tetrachloroethane reacts with concentrated sulphuric acid, at 100-160°C., to give monochloroacetic acid.[36]

Anhydrous tetrachloroethane may be employed as cooling medium for cold storage. To prevent evaporation of the halide, the latter is covered with a layer of glycerol or glycol, and to inhibit formation of corrosive acid, calcium, sodium or lead oxide is incorporated.[37]

Starr and Beiswenger[38] point out that a solvent mixture composed of phenol and tetrachloro derivatives is applicable for processing mineral oils.

In one method for the manufacture of motion picture films, cellulose acetate is dissolved in dichloroethylene and propyl alcohol, to which is added tetrachloroethane. The function of the latter, which has a higher boiling point than the olefin chloride, is to improve the mechanical properties of the resulting film.[39]

FIG. 161.—Method for Bromination of Saturated Gaseous Hydrocarbons. (W. J. Perelis)

Sullivan[40] suggested a combination of carbon tetrachloride, tetrachloroethane, naphtha and a small amount (0.1-2 per cent) of a chlorinated derivative of naphthalene as a dry cleaning fluid. Grebe and Mills[41] recommended tetrachloromethane and tetrachloroethane for the same purpose. This latter composition was reported to be noninflammable and nonexplosive and to evaporate from the articles cleaned in less than 5 minutes. Lindner[42] uses gasoline and tetrachloroethane as a dry cleaning agent. Reddish[42a] points out that the addition of water to chlorinated hydrocarbons used in dry cleaning will effect the removal of water-soluble soil and oil-soluble soil in one operation. To overcome the possibility of "water-spotting" the fabrics during cleaning, he suggests an "absorbefacient"[42b] to maintain the moisture present in a dispersed state. One such "absorbefacient" consists of 25 per cent oleic acid, 25 per cent naphtha and 50 per cent mahogany sodium sul-

[42b] An "absorbefacient" is a composition which dissolves in a cleaning solvent and which, though it does not readily absorb any substantial amount of moisture, renders the cleaning solvent capable of absorbing moisture.

phonate.[42c] In the cleaning operation a concentration of 6 per cent of the above compound is employed, together with a quantity of moisture equal to 5-15 per cent of the weight of the garments to be cleaned.

According to Balázs an atmosphere containing tetrachloroethane and trichloroethylene in the ratio 4:1 is very effective as an insecticide.[43] Another agent consists of finely powdered derris root, solid hexachloroethane and chalk.[44] Yamazaki[45] prefers a mixture of borax, hexachloroethane and a hydrofluoric acid solution of glass for the same purpose.

BROMINATION OF ETHANE

Merz and Weith[46] predicted, from experiments on the bromination of ethyl iodide, that the bromination of ethane would lead to tetrabromo- and hexabromoethane. Perelis,[47] on the other hand, reports that at a sufficiently low halogen concentration, mixtures of ethane and bromine (using an iron catalyst) lead mainly to the formation of monohalides, when the reaction temperature is maintained at 350°C. In effecting such an operation gaseous ethane was bubbled through a layer of liquid bromine, and the resulting mixture conducted through the heated reaction zone. To maintain a constant depth of liquid, fresh bromine was added intermittently throughout the reaction. Some of his results are shown in Table 156.

TABLE 156.—*Bromination of Ethane at 350°C.*

22	23.61	84.5	15.5

FLUORINATION OF ETHANE

Direct fluorination of methane homologues has not been reported. However, the preparation of fluoro-halo derivatives has received attention. For example, hydrogen fluoride will unite with dichloroethane when a catalyst such as ferric chloride and activated carbon is used.[48] Other contact agents include a halide of copper, silver, gold, zinc, cadmium, mercury, vanadium, manganese, cobalt, nickel or platinum dispersed in carbon which serves as a carrier.[49] Daudt and Youker[50] combined antimony pentachloride with hydrogen fluoride and added trichloroethane to yield monofluorodichloroethane. The presence of a liquid medium which is not reacted upon by fluorine, such as anhydrous hydrogen fluoride at —40°C., is recommended for the substitution of fluorine in tetrachloroethane.[51] Henne[52] prepared trichlorotrifluoroethane by reacting antimony trichloride with hexachloroethane and then treating the resulting compound with fluorine or hydrogen fluoride. The same investigator[53] points out that antimony trifluoride and chlorine may be employed in a similar method.

[42c] The mahogany sulphonates are discussed in Chapter 46.

Also, it has been suggested that mercuric fluoride be employed to effect the substitution of fluorine in an alkyl halide.[54] Thus, the preparation of ethyl fluoride from ethyl bromide and mercuric fluoride was reported. The apparatus consisted of a copper reaction vessel equipped with a copper reflux condenser. The latter was kept at 0°C. throughout the reaction. Ethyl bromide was placed in the vessel and mercuric fluoride slowly added. During the incorporation of the mercuric salt, the reaction vessel was immersed in an ice bath. It was stated that ethyl fluoride is generated as soon as the reagents come in contact. This halide passes through the reflux condenser and may be collected in a receiver cooled with solid carbon dioxide, while ethyl bromide is returned by the condenser to the reaction chamber. The yield of ethyl fluoride was said to be quantitative, all the salt left in the reaction vessel being mercuric bromide.

Properties of Fluorinated Ethane. The work of Henne and Midgley[55] indicates that the monofluoride and 1,2-difluoride of ethane are relatively unstable, readily undergoing hydrolysis and further fluorination. However, as soon as two fluorine atoms are attached to one carbon, the compound becomes stable and can be fluorinated further with difficulty. This effect is noticeable not only on the atom to which the fluorine is bound, but also upon the adjacent carbon.

The melting points, boiling points, densities and indices of refraction (for the red, yellow and blue lines, respectively) of some fluorohaloethanes have been compiled by Henne and his coworkers.[56] They are listed in Table 157.

THE CHLORINATION OF PROPANE

The chlorination of propane has been achieved by two general methods, (1) thermal treatment in the absence of light and oxygen and (2) in the presence of catalysts.

Chlorine and propane may be separately preheated to 100°C. and mixed in enameled metal or Pyrex glass chambers, without exposure to light. The product of the reaction is propyl chloride.[57] The process may be varied by passing a stream of chlorine into a current of the hydrocarbon at the above temperature.[58] To avoid explosion, the propane is present in excess and the speed of the chlorine is greater than the critical velocity at which ignition would occur.[59] Britton, Coleman and Hadler[60] report that during chlorination of propane some hydrogen chloride and propene are formed. However, by raising the temperature to 195-199°C. these two can be combined to give the saturated halide.

FIG. 161A.—Flow Diagram for Chlorination of Propane. (H. B. Hass, E. T. McBee, G. E. Hinds and E. W. Gluesenkamp)

Deanesly[61] has made a study of certain of the factors which influence the halogenation of propane. He states that oxygen inhibits the reaction, whether the latter be catalyzed by light or by olefins simultaneously reacting. This effect is utilized in one process in which addition, rather than substitution, is desired. Thus, a mixture of unsaturated and paraffin hydrocarbons is treated with a halogen and oxygen to give olefin halides.[62] According to the above investigator[63] chlorination of propane can be brought about by adding free chlorine in the dark, in the absence of oxygen, and below 100°C. A small amount of an olefin (propene) in the reaction chamber is reported to increase the speed of substitution. The chlorination of a mixture of propane and 1-monochloropropane has been utilized to prepare 1,3-dichloropropane.[63a] In the procedure an excess (10:1) of the hydrocarbon and monohalide over chlorine was maintained to inhibit the formation of trichloro derivatives. The chlorine was allowed to react completely, so that the product flowing to the condenser and rectifying column (Fig. 161A) consisted of 1- and 2-monochloropropane, 1,1-, 1,3-, 1,2-, and 2,2-dichloropropanes, as well as hydrogen chloride. Because of the widely separated boiling points of these substances (Fig. 161B), removal of a relatively pure 1,3- derivative at 120.4°C. was said to be effectively accomplished. The latter compound was employed in the synthesis of cyclopropane, used as an anesthetic.[63b]

The catalytic chlorination of di- and tri-chloropropanes has received attention,[64] but relatively few reports on direct halogenation of the hydrocarbon (propane) by the aid of contact agents have been noted. Sharp[65] points out that cupric or ferric chloride will aid the chlorination of propane if mono- and dichloropropane are also present. The use of actinic rays and of successive reaction stages at progressively higher temperatures is recommended in this procedure.

In the monochloride fraction which Schorlemmer[66] obtained by the photochemical chlorination of propane, he reported only 1-chloropropane. Later work by Hass, McBee and Weber[67] indicates that with the use of more modern rectification equipment a yield of 60 per cent 2-chloropropane and 40 per cent 1-chloropropane can be obtained.

Yuster and Reyerson[68] show that the homogeneous (single phase) chlorination of propane is of the chain type, as evidenced by an induction period, the inhibitory effect of oxygen and the fact that a packed chamber reduces the extent of halide formation. They conclude that the complete picture is extremely complicated and is an eight-stage process with an enormous number of combinations in the intermediate stages. High partial pressures of propane eliminate explosions and favor the production of monochloropropane (75 per cent), with a conversion of 90 per cent of the chlorine input.

The heterogeneous reaction in the presence of aluminum oxide, copper and cupric chloride deposited on a silicon dioxide gel is described by the same investigators.[69] The extent of chlorination increases with a rise of temperature, but when complete conversion is attained, the temperature can be reduced without diminishing the yield of halides. High partial pressure of chlorine, rising temperatures and greater rates of flow lead to di- and trichloropropanes, but tend to render the catalyst inactive. The view that secondary chlorination of the propene (arising from the pyrolysis of propyl chloride) takes place is supported by the fact that a large proportion of 1,2-dichloropropane is obtained.

Uses of Chlorinated Propane. Propene chloride is used with methyl or ethyl alcohol in the preparation of lacquers containing cellulose acetate.[70] 1,2-Dichloropropane and methanol are not individual solvents for cellulose acetate, but solvent action is obtained when a composite of the two containing 70 per cent of the halide and 30 per cent of the alcohol is employed. When mixed with carbon tetrachloride, the former is reported to be superior to carbon disulphide as a fumigant.[71] Also, 1,2-dichloropropane has been employed together with dichloropropene in dewaxing oils.[71a] As a dry cleaning agent, trichloropropane has been suggested.[72] One of the reported advantages of this substance is its relatively low toxicity and the fact that it is non-flammable.

CHLORINATION OF BUTANE

According to Deanesly[72a] the formation of mono- and dichlorobutanes from chlorine and butane in the absence of light is induced if butene is simultaneously introduced into the reaction zone. Oxygen is excluded and the temperature range may be extended from —41° to 100°C. Clark[72b] points out that butane may be halogenated in the vapor phase by admixing the hydrocarbon and chlorine. The products are led to a fractionating column where the halogenated derivatives are separated. Hydrogen chloride and unreacted butane may then be recycled to act as a reflux. For a continuous-flow process involving vapor phase operations and acceleration by actinic light, isobutane and chlorine are conducted at 250°C. through a reaction chamber, the walls of this chamber being maintained at 200°C. The vapors are kept in contact for a period of 10 seconds and the products rapidly cooled at 100°C. at the end of that time. In this manner the production of olefins and chloroölefins is said to be prevented.[72c]

According to Nutting, Britton, Huscher and Petrie,[73] *ter*-butyl chloride may be obtained by heating isobutyl chloride (vapor) to 300°C. with a catalyst (anhydrous ferrous chloride) to dissociate it to isobutene and hydrogen chloride. These vapors are passed over aluminum oxide at 150°C. to form the desired product.

Hass, McBee and Weber[74] show that the chlorination of *n*-butane yields 1-chloro and 2-chlorobutane as monochlorides and a mixture of 1,2-dichloro- and 1,3-dichlorobutane as dichlorides, indicating the lack of evidence for carbon skeleton rearrangement such as an isobutyl chloride resulting from the chlorination of *n*-butane.

Further chlorination of 2-chloro-2-methylpropane is reported to lead to a number of chlorine derivatives of isobutane.[75] The halogenation was effected in the liquid phase under a reflux condenser employing ordinary incandescent lamps for activation. The hydrogen chloride formed in the process was absorbed in ice water to prevent loss of the volatile halides. The products secured from the reaction may be represented by

Uses of Chlorinated Butane. Among the uses for which monochlorobutane has been proposed is the preparation of butylcellulose.[76] In the procedure, 10 moles of monochlorobutane, 1 mole of mercerized cellulose, and 8 moles of aqueous caustic soda, containing 40-50 per cent of sodium hydroxide, are heated together to 123-125°C. The temperature is maintained at this point for 12 hours. The butylcellulose formed is said to contain 2 butyl groups per molecule and to constitute 80-89 per cent of the theoretical yield. 1,3-Dichloro-2-methyl propane is employed as a diluent in removing wax from mineral oils.[77] 2,3-Dichlorobutane is recommended as a solvent for fats, for its corrosive action on metal containers, while slightly greater than that of dichloroethane, is reported to be less than trichloroethylene.[78] To de-ink paper containing a carbon ink, Hass[79] uses an aqueous soap solution containing 1,3-dichloroisobutane.

FLUORINATION OF BUTANE

Desreux[80] reports the formation of butyl fluoride from butyl iodide and mercurous fluoride, the reaction taking place in a copper flask. According to the above investigator some of the properties of the halide are as follows: boiling point (745.8 mm.) = 31.95-31.98°C., density at 20°C. = 0.7761, indices of refraction, $n_\alpha^{15} = 1.3404$, $n_D^{15} = 1.3419$, $n_\beta^{15} = 1.3457$, $n_\gamma^{15} = 1.3488$ and the viscosity at 20°C. = 0.002845.

CHLORINATION OF PENTANE

To secure monochloro derivatives of pentane, Teichmann, Klein and Rathemacher[81] treat pentane with liquid polychloro hydrocarbons (trichloropentane) by exposure to ultraviolet light. The products are reacted with chlorine under pressure (to prevent inception of a vapor phase) and the monochloropentanes separated from the dichloropentanes by fractionation. At a temperature of 86-90°C., the pentane fraction of gasoline, combined with chlorine in the proportion 6:1 by volume, yields 90 per cent of monochloropentane. A rise in the concentration of chlorine favored the formation of dichloropentane.[82]

When Wertyporoch[83] chlorinated *n*-pentane he obtained a monochloride boiling at about 97°C., and reported the presence of both primary chlorides of isopentane. Hass and Weber,[84] on the other hand, point out that no derivatives of isopentane can be present in the chlorides obtained from *n*-pentane. They support their contention with two considerations: (a) the very much slower rate of metathesis with potassium iodide shown by the secondary chlorides of *n*-pentane as compared to those of the primary chlorides of isopentane[85] and (b) the fact that the mixtures of anilides derived from the secondary chlorides of *n*-pentane have melting points which correspond exactly to the composition calculated from the rule which states that secondary and tertiary hydrogen atoms are always substituted more quickly than primary.[86] For if any of the chlorides of isopentane were present they would cause the melting points to differ from the values previously determined with varying proportions of the chlorides of *n*-pentane.

Uses of Chlorinated Pentane. The substitution of chlorine in mixed pentanes leads to the formation, in addition to the paraffin halides, of 3,5,5-trimethylheptene-2 and 3,4,5,5-tetramethylhexene-2.[88] Dichloropentane, containing small proportions of phenol, ethyl alcohol and benzene, has been suggested as a paint and varnish remover.[89] A process for the production of alcohol from pentyl chloride has been reported.[90] The halide is treated with a salt of a non-corrosive fatty acid of high boiling point (sodium stearate) to form the ester of an alcohol. The latter is subsequently recovered by hydrolysis.[91] Also, the halogenated pentane may be admixed with caustic solution and amyl oleate[92] to secure amyl alcohol.[93]

Cracked gasoline, when chlorinated and treated with a lead-sodium alloy, furnishes a metallo-organic derivative which is said to be valuable as an antiknock agent for automobile fuels.[94] These metallo-organic compounds may be formed by reacting the chlorinated gasoline with magnesium to form a Grignard reagent, which is then united with the lead-sodium alloy. One of the reported advantages of this procedure is that the antiknock compound may be prepared in the gasoline, thus minimizing the danger of industrial poisoning associated with the manufacture of lead compounds employed to suppress knocking.[95]

Chlorinated gasoline has been proposed as a partial solvent for substances used in coating compositions.[96] Thus, aluminum stearate and aluminum hydroxide are incorporated in a quantity of halogenated gasoline sufficient to dissolve a portion of the mixed salt and base and to maintain the remainder in suspension.

Monochloropentane has been reported to be an anisotropic substance.[97] Evidence for this conclusion was obtained by measuring the amount of depolarization of polarized light when the latter was diffused by the halide. It was found, in this instance, that the light was only partially polarized on diffusion.[98]

CHLORINATION OF HIGHER PARAFFIN HYDROCARBONS

The increment in molecular volume upon chlorination of higher paraffins has been utilized to determine the mechanism of reaction.[99] With a paraffin melting at 46-51°C. the increase in molecular volume on halogenation was stated to be directly proportional to the chlorine content of the product. From this the inference was drawn that chlorination of a saturated long chain hydrocarbon is a substitution, rather than an addition, mechanism. Further, halogenation of high-molecular-weight paraffins was reported to result in a pronounced lowering of the melting point and increase in viscosity of the product.[100]

Tanaka, Kobayashi and Furihata[101] plotted the chlorination curves of liquid paraffins to relate reaction time, temperature and the amounts of hydrogen chloride formed. They pointed out that these reactions show an induction period, a gradual increase in the velocity, a maximum reaction velocity, and a sharp decrease in speed to a constant value. This indicates a chain mechanism consisting of a period of activation and one of chain reaction, with the maximum velocity at the transition point of the two.

Formation of resins by chlorination of petroleum tar and subsequent removal of the halogen as hydrochloric acid have been effected.[102] For example, a cracked tar boiling between 330° and 600°F. at 1 mm. was chlorinated at 72-150°F. until the weight of the paraffin increased 10-15 per cent. The chlorinated product was distilled at 660°F. at 760 mm. and then at the same temperature under a pressure of 1 mm. The overhead was said to consist mainly of hydrochloric acid and the oily constituents of the halogenated tar. The residue was cooled to 200°F. and extracted with naphtha to remove the resinous products.

A liquid paraffin from the refining of a Russian engine oil, when combined with chlorine, furnishes a mono-chlor substitution derivative.[103] The product is heavier and more viscous than the original oil, yellowish-green in color, odorless and tasteless. Gallsworthy[104] secured a saturated halide by subjecting lubricating oil to the action of a mixture of hydrochloric and hypochlorous acids at 150°F. (65°C.) under a pressure of 25 pounds per square inch. In the procedure, water and chlorine are admixed in equivalent proportions to form chlorine water (a mixture of hydrochloric and hypochlorous acids). The latter is then conducted to a reaction chamber where it is united with the oil under the conditions mentioned above. The products of the reaction are conducted to a settling chamber where the partially used chlorine water is separated. This chlorine water may be employed to halogenate in part another portion of the oil. (See Fig. 163.) Barth[105] utilizes the reaction of chlorine and a liquid paraffin to secure a substituted halide. The two are united at 180°F. over water containing magnesium or calcium carbonate; the purpose of the latter is to unite with the hydrochloric acid liberated.

Sulphur dioxide and chlorine have been employed to effect the preparation of a halogen derivative of a paraffin wax which was assumed to consist mainly of tetracosane, $C_{24}H_{50}$. Thus, the paraffin was heated to 90-95°C. and a mixture of sulphur dioxide and chlorine bubbled through the resulting liquid.[106] When the weight of the paraffin had increased 20-25 per cent, the temperature was reduced to 40-50°C. for further chlorination. The product was a moderately viscous oil, light yellow in color, and liquid at 20°C. The presence of sulphur dioxide was said to promote substitution on adjacent carbon atoms, so that the resulting paraffin halide could be hydrolyzed to a polyhydric alcohol.

To chlorinate the isomers of hexane and octane in a mixture of normal and

isomeric types, Moldavskii and Livshitz[107] recommend a 0.5*N* solution of antimony pentachloride in chloroform. This will react with the isohexanes and isoöctanes, but not with the *n*-paraffins. A process for preparing pure alkyl chlorides of high molecular weight from the corresponding aliphatic alcohols is reported by Schrauth,[108] who states that all chloro-paraffins with an even number of carbon atoms, from octyl to docosyl (C_{22}) have been synthesized. These higher-molecular halogen alkyls are water-white oils of high boiling point and relatively high flash point, and can be heated to 250-300°C. without decomposition. The density of the oils diminishes with increase in molecular weight and varies between 0.875 and 0.860.

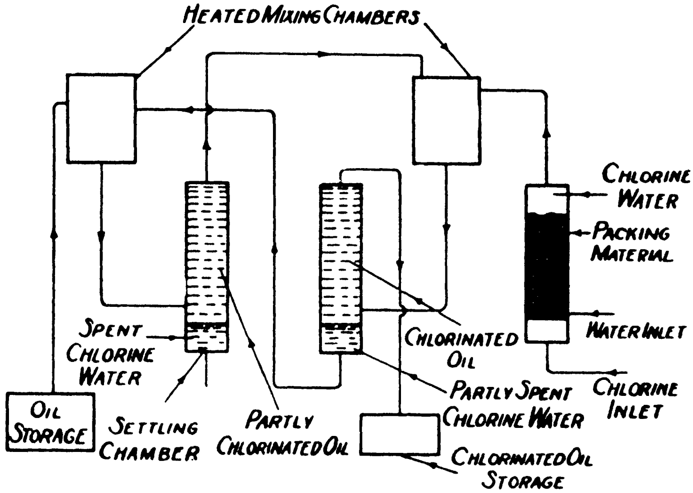

FIG. 163.—Diagram of Method for Chlorination of Hydrocarbon Oils. (B. Gallsworthy)

Properties of Higher Chlorinated Paraffins. Strauss[109] compared the chlorine compounds obtained from soft with those from hard paraffin waxes and found that for the same percentage of chlorine the products from soft wax have lower specific gravities, viscosities and flash-points than those obtained from hard waxes. For both classes these properties increase with further chlorination. The chlorinated waxes are miscible in all proportions with heavy oils, and promote the solubility of castor oil in mineral oils.

Uses of Chloro Derivatives of Higher Paraffin Hydrocarbons. Herbsman[110] reports the use of "chlorocosane" (chlorinated paraffin wax) for breaking petroleum emulsions. A small quantity of the former is added to the emulsion, and the resulting composite is electrically dehydrated.

A method of manufacturing lubricants consists of separation of a mixture of hard or soft paraffins of high carbon content into two fractions with different mean molecular weights. Halogenation and subsequent condensation by the action of a catalyst (e.g., alumina)[111] bring about the formation of the lubricant. A small portion of a synthetic oil, obtained by condensing chlorinated paraffin wax and benzene in the presence of a contact agent (aluminum chloride) is added to heavy transmission gear lubricants to increase the effectiveness of the latter.[112] This synthetic product (of the "Paraflow" type) is recommended by Anderson[113] for dewaxing oils of large molecular weight. The separation of the more active "Paraflow" from the remaining reaction products is said to be accomplished by extraction with a wax precipitant such as butanol or pentanol.[114] Zimmer, Davis and Frolich[115] report that small amounts of wax cause congealing of oil at relatively high temperatures by a twofold action: (a) interlocking wax crystals prevent the free flow of the lubricant and (b) they retain adsorbed oil, causing the formation of a type of gel. The action of "Paraflow" consists in its adsorption on the surface of the wax particles, inhibiting the growth of larger crystals of the latter and causing it to lose its attraction for the oil. "Paraflow" lowers the pour point of Diesel fuels of low paraffin content to −30°C. if an excess of aromatic oils with high melting points is not present.[116] Condensation of diphenylene oxide with a chlorinated paraffin in the presence of aluminum chloride is recommended to prepare a pour point depressant for lubricating oil.[117] In some cases, metallic aluminum is employed to effect condensation.[118] Thus, chlorinated decane is treated with benzene or naphthalene in the presence of the above catalyst to secure a colored substance which is said to impart fluorescence to lubricating oils. To procure wetting and emulsifying agents, Keller and Gofferjé[119] treated polychlorinated hydrocarbons with alkalies and sulphonates, obtaining products containing sulphonic and bisulphate groups. A high or "extreme" pressure lubricant of one process comprises mineral lubricating oil, free sulphur and chlorinated paraffin wax.[120] Also, chlorinated hexane is stated to improve the lubricating properties of mineral oil.[121] Chlorinated hydrocarbons containing more than 9 carbon atoms and at least 2 halogen atoms in a molecule may be reacted with alkalies to obtain a drying oil.[122] For example, a chlorinated solid paraffin having a molecular weight of 367 and containing 14 atoms of chlorine per molecule was heated for 10 hours in an autoclave with aqueous calcium hydroxide. At the end of the reaction period, the products were cooled to 20°C. and the oil separated from the alkaline solution. The oil was then washed with slightly acidulated water and dried. On exposure of the oily product in a thin layer in the air, an elastic film of high luster was said to be secured. Monohalogenated paraffin wax may be reacted with a mixture of potassium acetate and acetic acid, or potassium stearate, butanol and sodium iodide, or of dibutylamine and xylene to yield plasticizing or impregnating agents.[123]

Also, it has been suggested that the addition of a small proportion of chlorinated paraffin with a molecular weight above 200 to castor oil will render the latter soluble in mineral oil.[124] A coating composition applicable to metals is reported to be furnished by admixing 20 parts of chlorinated rubber and 15 parts of chlorinated paraffin in 65 parts of carbon tetrachloride.[125]

BROMINATION OF HIGHER HYDROCARBONS

According to André and Maurel[126] the bromination of liquid paraffins is more difficult than chlorination, and at best only two-thirds of the theoretical amount of bromine necessary to form a monobromo substitution product can be introduced. Attempts to accelerate the halogenation with various metals were unsuccessful. The product was a brown viscous liquid, which, on standing in a stoppered flask, deposited a powder redissolvable on shaking at 30-35°C. This powder contained 33.5 per cent of bromine, corresponding to a replacement of two hydrogen atoms in a substance of a mean molecular weight of 380.

Uses. Whitmore, Stehman and Herndon[127] report a yield of 10 per cent hexamethylethane from pentamethylethyl bromide in a xylene solution of methylmagnesium chloride (Grignard Reagent) and one of 50 per cent from the same bromide in a xylene solution of zinc dimethyl. The product was employed in studying intramolecular arrangement.

FLUORINATION OF HIGHER HYDROCARBONS

Paraffin wax is fluorinated by treatment, at the boiling point of the solvent (benzene), of a chlorinated solid paraffin with antimony trifluoride and antimony pentachloride, avoiding an excess of the fluoride. The resulting halide is a chemically stable liquid which may be used as a dielectric.[128] Also, it has been stated that a mixture of petroleum hydrocarbons may be fluorinated by conducting a finely divided solution of fluorine gas into the petroleum.[129] The fluorine is prepared by electrolyzing fused potassium bifluoride which contains less than 0.05 per cent of water.

Chapter 31

Halogenation of Cycloparaffins

Halogenation of the cycloparaffin hydrocarbons occurring in crude petroleum apparently has not been investigated to the same extent as that of the straight chain and aromatic compounds. A possible reason for the scarcity of information may be that the proportion of such saturated cyclic hydrocarbons in many crude petroleums, or their distillates, is much less than that of either paraffins or aromatics. Furthermore, separation of individual cycloparaffins from other admixed hydrocarbons is a difficult operation. Most of the available information is the result of work done with a petroleum fraction having a narrow boiling range, generally from Russian or Rumanian oils, and containing a preponderance of one hydrocarbon.[1]

The name naphthene has been applied as a general term to include all saturated cyclic hydrocarbons. Originally this term was meant to specify only those substances which contained a saturated 5-membered or cyclopentane ring. As a matter of convenience, naphthene has been extended to cycloparaffins in general, such as cyclopropane, cyclobutane, cyclopentane, cyclohexane and cycloheptane.

The action of halogens on naphthenes seems to be similar to that with straight chain hydrocarbons and leads to the production of chloro or bromo compounds containing one or more halogen atoms. However, this similarity exists particularly in the 5- and 6-membered rings, for in the case of cyclopropane and cyclobutane and their homologues, halogenation is frequently associated with an addition reaction leading to the rupture of the ring and the formation of halogenated straight chain hydrocarbons. For example, cyclopropane yields not only the monochloro derivative but also 1,3-dichloropropane.

Chlorination of the cyclopentane and cyclohexane rings appears to take place much more readily than does bromination, especially in the presence of sunlight or other actinic light. The reaction appears to be of a cumulative nature, prolonged treatment giving rise to the formation of polychlorinated products. The presence of catalysts also favors multiple substitution. Bromine will replace hydrogen in cyclopentane or cyclohexane if reactions are carried out above 100°C., but the yield of monobromides is rather poor. In the presence of contact agents, such as aluminum bromide or iron wire, bromination takes place more readily and, if a large proportion of bromine is employed, frequently converts cyclohexane hydrocarbons into polybrominated derivatives of benzenoid hydrocarbons. Furthermore, chlorine and bromine derivatives of the naphthenes may be prepared from the corresponding alcohol by the action of hydrochloric or hydrobromic acids, phosphorus pentachloride or bromide, and phosphorus trichloride or bromide. Addition of bromine or chlorine to an unsaturated naphthene, such as cyclopentene or cyclohexene, will likewise result in the formation of halocycloparaffins.

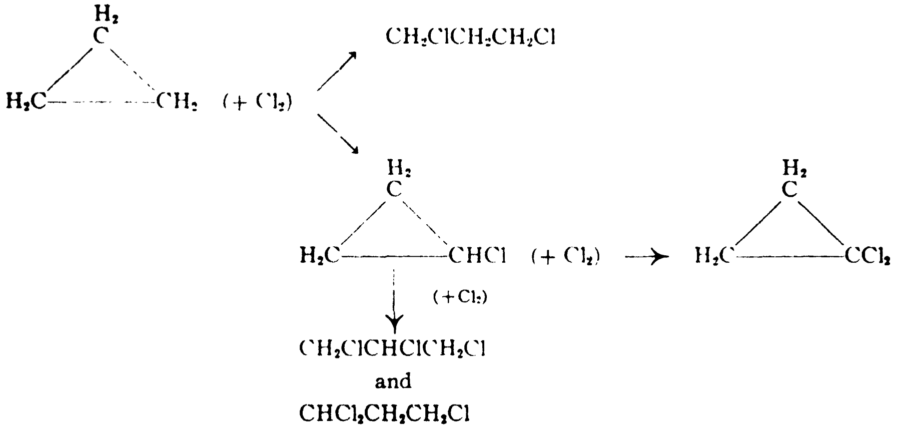
The substituted derivatives of the naphthenes exhibit a degree of reactivity which is comparable to that of the halogen derivatives of the straight chain hydrocarbons. For example, they may be hydrolyzed to yield a secondary alcohol, decomposed to unsaturated naphthenes by the action of quinoline, converted into cycloalkylamines by reaction with aniline, or combined with magnesium to form Grignard reagents.

---

[1] See, Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., Inc., New York, 1934.

CYCLOPROPANE

Investigations on the photochemical chlorination of cyclopropane show that although no chlorination occurs in the dark, in direct sunlight the reaction is explosive.[2] Accordingly, diffused daylight has been employed to activate the reactants. Under these conditions the compounds produced included not only mono- and 1,1-dichlorocyclopropanes, but also 1,3-dichloro- and 1,1,3-trichloropropane, showing that there is a tendency of the ring to be ruptured. Halogenation of cyclopropane in diffused daylight may be summarized in the following scheme:



Bromination of cyclopropane in actinic light leads to the formation of a straight chain compound, 1,3-dibromopropane. Halogen carriers, such as aluminum halides, hydrogen bromide, ferric and zinc chlorides, materially increase the rate of addition in the absence of light. In this case also the products consist of 1,3- and 1,2-dibromopropane. It will be seen, therefore, that the cyclopropane ring structure is rather easily ruptured by the action of bromine under the conditions which have been studied.[3] Nicolet and Sattler[4] have proposed a mechanism to account for the addition of bromine when hydrogen bromide is employed as a catalyst. They state that the reaction proceeds by two stages: (1) substitution of bromine in the cyclopropane ring, followed by (2) addition of hydrogen bromide to the substituted naphthene, with a resulting rupture of the ring structure and formation of a dibromopropane.

It is of interest to note that indirect methods have also been proposed for the preparation of halogenated cycloparaffins. For example, cyclopropene is reported to react vigorously with bromine to yield dibromocyclopropane. The reaction is carried out in the cold and in the presence of carbon monoxide, which serves as a diluent.[5] The resulting dihalogenated cyclopropane boils at 45°C. under 27 mm., at 135-136°C. under 743 mm., melts in the range —1° to + 1°C., has d_4^{20} 2.1040 and n_D^{20}1.5369.

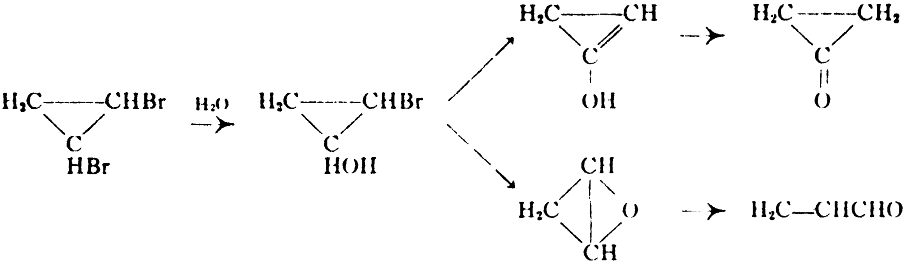
---

[2] Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., Inc., New York, 1934.

[3] The relative instability of rings of less than 5 or 6 members is indicated by R. Willstätter and J. Bruce, (*Ber.*, 1907, 40, 4456; *J.C.S.*, 1907, 92 (1), 1018; *Chem. Abs.*, 1908, 2, 398), who stated that the hydrogenation of cyclopropane in the gaseous phase over a nickel catalyst at 120°C. gave propane. In this connection, see Carleton Ellis, "Hydrogenation of Organic Substances," Third Edition, D. Van Nostrand Co., Inc., New York, 1930, Chapter 20.

[4] B. H. Nicolet and L. Sattler, *J.A.C.S.*, 1927, 49, 2066; *Chem. Abs.*, 1927, 21, 3046; *Brit. Chem. Abs.* A, 1927, 1068.

The action of water upon the dibrominated derivatives of cyclopropane does not seem to result in the formation of an alcohol. Dem'yanov and Doyarenko[6] reported that heating dibromocyclopropane with water (in sealed tubes) at temperatures between 105 and 165°C. gives acrolein (acrylaldehyde) and a dark hard substance, insoluble in ether or ethanol and containing 76 per cent of carbon, 6.4 per cent of hydrogen and 17.6 per cent of oxygen. Since this analysis corresponds to the formula C_6H_6O, these investigators believed the solid was formed by the condensation of two molecules of acrolein. A mechanism was proposed to show the action of water on dibromocyclopropane as follows:



When distilled in the presence of zinc dust, dibromocyclopropane is said to lose bromine and form cyclopropene.[7]

CYCLOBUTANE

Apparently very little is known about the halogenation of cyclobutane or its homologues, though this hydrocarbon is said to be stable to halogens in the cold.[8] However, a number of indirect methods for preparing the chlorides or bromides have been proposed and the reactions of the resulting halides have been studied.

Dem'yanov[9] reports that cyclobutanol when treated with concentrated hydrobromic acid at 70°C. for a period of 20 minutes yields a monobromide, C_4H_7Br. This was converted into the magnesium derivative and then reacted with carbon dioxide to furnish a carboxylic derivative said to be cyclopropyl acetic acid. Thus it appears that the ring structure is changed from one of 4 carbons to one of 3 by the action of hydrobromic acid. Cyclobutene does not suffer degradation of the ring structure upon treatment with chlorine or bromine, but readily forms dichloro- and dibromocyclobutane when diffused daylight is employed to energize the reactants.[10] Acids have also been suggested for the preparation of dibromocyclobutane. For example, bromine and caustic potash combine with α-bromotetramethylenecarboxylic acid to furnish cyclobutanone and 1,1-dibromocyclobutane.[11]

Hydrolysis of mono- and dihalocyclobutanes to produce alcohols has not been reported. Kishner[12] states that dibromocyclobutane is converted to cyclobutanone when heated with lead oxide and water at 100°C. The dibromide will react with quinoline to furnish butadiene, and with potassium hydroxide at 210°C. to form acetylene. If the temperature is lowered to 100°C. then 1-bromocyclo-1-butene is furnished. The latter may be oxidized with potassium permanganate in neutral alcoholic solution, and the intermediate product oxidized with chromic acid to succinic acid. The various steps may be represented by:

Dibromocyclobutane is said to react with bromine in the presence of iron with subsequent ring rupture to yield tetrabromobutane.[13] This may be further brominated in the presence of iron, in which case it splits off a molecule of hydrogen bromide, forming an oily product containing hexabromocyclobutane.

The stability of the cyclobutane ring has been investigated by Rozanov[14] who subjected methylcyclobutane to the action of a number of reagents. When it was agitated with fuming hydrobromic acid for 5 hours, methylcyclobutane reacted to form 2-bromopentane. With hydriodic acid, 2-iodopentane was obtained. Bromine, mixed with the methylcyclobutane in sunlight, gave 1,4-dibromopentane. From these experiments the conclusion was drawn that a ring containing 4 carbon atoms is no more stable to the three reagents mentioned above than was cyclopropane, a 3-carbon ring.[15]

CYCLOPENTANE

The published data on the preparation of halogen derivatives of cyclopentane do not present any methods for the direct chlorination or bromination of this cycloparaffin. Nevertheless, a number of halogen substituted cyclopentanes have been prepared by indirect methods.

Monochlorocyclopentane can be made by heating cyclopentanol with concentrated hydrochloric acid (under reflux) for a period of 3 hours.[16] A trichlorocyclopentane has been obtained from the interaction of monochlorocyclopentene and chlorine, and a tetrachloride by chlorination of cyclopentadiene in chloroform solution at −15°C.[17]

Among the uses which have been suggested for monochlorocyclopentane are included the preparation of methyl cyclopentyl carbinol and of cyclopentene. Edwards and Reid[18] state that the alcohol may be secured by combining the chloride with magnesium to form a Grignard reagent which is then reacted with acetaldehyde. In the procedure, 150 cc. of ether and 18 g. of magnesium turnings were placed in a flask fitted with a reflux condenser. To this was added an ethereal solution of monochlorocyclopentane containing 77 g. of the latter substance. The mixture was cooled, refluxed on a water bath for 1 hour and again cooled, forming cyclopentyl magnesium chloride. A solution of 33 g. of acetaldehyde in ether was incorporated with the Grignard compound and allowed to stand for 12 hours. At the end of that period the mixture was refluxed for 15 minutes, acidified with hydrochloric acid, and the ethereal layer extracted. The ether was distilled off and the residue fractionated, the portion boiling at 85-85.5°C. being retained. The complete reaction may be expressed by the mechanism

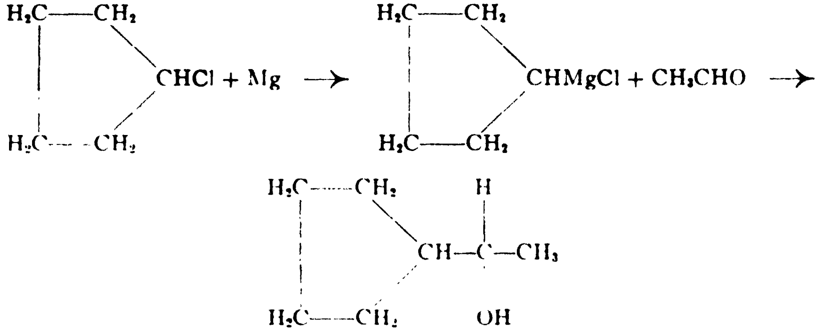
[18] W. R. Edwards, Jr., and E. E. Reid, *loc. cit.*



The preparation of cyclopentene is said to be effected by conducting chlorocyclopentane vapors, under a pressure of 15 to 20 mm., over a bed of barium chloride which is heated to 300-400°C.[19]

Monobromocyclopentane may be obtained by heating cyclobutylmethanol with hydrogen bromide at a temperature of 100°C.[20] During this operation isomerization of methylcyclobutanol to the corresponding cyclopentane derivative apparently took place. This assumption was further substantiated by reduction of the bromide with zinc and palladium in hydrobromic acid to cyclopentane, b.p. 49-50°C. at a pressure of 750 mm. Noller and Adams[21] point out that cyclopentanol and phosphorus tribromide may be employed to secure monobromocyclopentane. To 172 g. of cyclopentanol, at 0°C., were added 192 g. of phosphorus tribromide, the mixture being stirred to maintain the temperature at 0°C. When incorporation of the latter compound was completed, the temperature was allowed to rise to 20°C. and held at that point for 12 hours. Water was then added and the mixture steam distilled. The distillate separated into two layers, the lower one being removed, dried and fractionated. The cut boiling at 135-136°C. consisted of monobromocyclopentane. Dibromocyclopentane may be prepared by combining cyclopentene and bromine in chloroform[22] or carbon disulphide.[23]

Monobromocyclopentane can be converted into cyclopentyl magnesium bromide in a manner analogous to that employed for the corresponding chloride.[24] By treating this Grignard reagent with formaldehyde, cyclopentyl carbinol is said to be produced. The cyclopentyl magnesium bromide may also be combined with propionaldehyde or butyraldehyde to furnish propyl or butyl cyclopentyl carbinols, respectively.[25]

CYCLOHEXANE

Chlorination. Investigations on the chlorination of cyclohexane have revealed that substitution of hydrogen in the cycloparaffin takes place when the hydrocarbon and halogen are exposed to diffused daylight. In this manner mono-, di-, tri- and tetra-chlorocyclohexane have been prepared. Low temperatures (0°C.) should be maintained and the use of catalysts is unnecessary.[26]

FIG. 164.—Apparatus for Photochlorination Reactions. (P. H. Groggins)

The photochemical reaction between cyclohexane and chlorine in dry carbon tetrachloride has been investigated by Basu.[27] The reactants were subjected to the radiation of a mercury arc lamp, and the course of the reaction was determined by adding potassium iodide to the solution and titrating the liberated iodine with sodium thiosulphate. The velocity constant was reported to be directly proportional to the intensity of the incident radiation and independent of the concentra-

[25] W. R. Edwards, Jr., and E. E. Reid, *J.A.C.S.*, 1930, **52**, 3235; *Chem. Abs.*, 1930, **24**, 4767; *Brit. Chem. Abs.* **A**, 1930, 1206.

tion of the chlorine. Incorporation of a small proportion of hydrogen chloride in the reaction zone was said to raise the value of the velocity constant. On the other hand, the latter was found to be diminished as the reaction proceeded under these conditions. The retarding influence exercised by the chlorocyclohexane which was formed was offered as a possible reason for the decrease in the velocity constant. The quantum efficiency[28] varied between 19 and 41, being greatest when the wave length of the light employed was 366 millimicrons and least when the wave length was 436 millimicrons. In explanation of the observed facts a mechanism has been suggested which may be represented as follows:

(1) $Cl_2 + h\nu$[a] $\longrightarrow Cl + Cl$
(2) $Cl + C_6H_{12} \longrightarrow C_6H_{11}Cl + H$
(3) $H + Cl_2 \longrightarrow HCl + Cl$
(4) $H + C_6H_{11}Cl \longrightarrow C_6H_{12} + Cl$
(5) $Cl + H \longrightarrow HCl$

[a] $h\nu$ is a quantum of energy.

The fourth equation is offered as an explanation of the cause of the diminution in the velocity constant as the reaction proceeds.

Thermal chlorination of cyclohexane has been recommended as an efficient method for preparing mono- and dichlorocyclohexane.[29] The chlorine and cyclohexane are separately preheated and when the temperature of the reactants has reached 450-550°C. they are forced into a reaction coil at high velocities. The coil in which the two substances are mixed is surrounded by a cooling medium to absorb the heat developed by the interaction. At the end of a contact time of 0.1 second the products are quickly cooled to 20°C. and the mono- and dichlorocyclohexanes are separated by fractionation. The relatively high velocity of the reactants on entering the coils was said to result in thorough mixing of halogen and cycloparaffin, and the short contact time was stated to prevent the occurrence of a flame with an attending deposition of carbon.

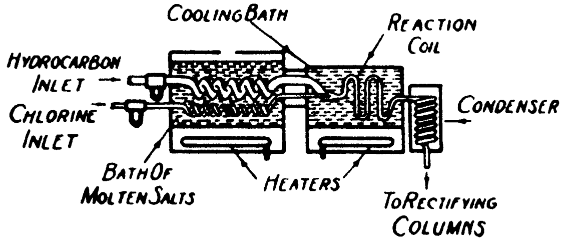

Fig. 165. Method for Thermal Chlorination of Hydrocarbons. (H. B. Hass and E. T. McBee)

Another procedure involves interaction of cyclohexanol with thionyl chloride, employing pyridine as a solvent.[30] In this manner a small proportion of monochlorocyclohexane is said to be obtained, together with a large proportion of cyclohexene. Also, 1,4-cyclohexanediol has been recommended.[31] In the latter case 1 mole of the diol is treated with 3 moles of hydrochloric acid at 100°C. for a period of 6 hours. The main product is 1,4-dichlorohexane together with smaller amounts of 4-chlorocyclohexanol. Chlorination of cyclohexene to 1,2-dichlorocyclohexane has also been advocated.[32]

---

[28] Quantum efficiency is the ratio of the number of molecules destroyed to the number of quanta of energy absorbed.

Uses of Chlorocyclohexanes. The chloro derivatives of cyclohexane undergo reactions which are similar to those of the alkyl and aryl chlorides.[33] Monochlorocyclohexane may be converted into a Grignard compound[34] by treating the former with magnesium.[35] Ether is employed as a solvent for the metal, to which monochlorocyclohexane is slowly added while the temperature is maintained at 0°C. When the addition of the chloride is completed, the temperature is raised to 20°C. The product may then be reacted with stannic bromide to form organometallic compounds. In one case the Grignard reagent is diluted with benzene, cooled to 0°C. in an ice-water bath, and the stannic bromide incorporated in the solution. The latter is then heated under a reflux condenser for 3 hours to form a mixture of tetracyclohexyl tin and hexacyclohexyldistannane.

$$4C_6H_{11}MgCl + SnBr_4 \longrightarrow (C_6H_{11})_4Sn + 2MgCl_2 + 2MgBr_2$$
$$6C_6H_{11}MgCl + 2SnBr_4 \longrightarrow (C_6H_{11})_3Sn{-}Sn(C_6H_{11})_3 + 3MgCl_2 + 3MgBr_2 + Br_2$$

The Grignard compound just described may also be employed to furnish (with carbon dioxide) cyclohexanecarboxylic acid which is reported to be a sedative.[36] Carbon dioxide transforms the cyclohexyl magnesium chloride into magnesium cyclohexanecarboxylate, from which the carboxylic acid may be obtained by treatment with a dilute mineral acid.

Monochlorocyclohexane may also be reacted with cycloparaffins in the presence of aluminum halides.[37] For example, Nenitzescu and Ionescu[38] condensed 365 g. of monochlorocyclohexane with 1300 cc. of cyclohexane, using 400 g. of aluminum chloride as catalyst. The temperature was maintained at 20°C. for a period of 3 days, at the end of which time 96 per cent of the theoretical amount of hydrogen chloride had been evolved. Two layers were formed, the upper consisting of cyclohexane admixed with other hydrocarbons. This mixture was fractionated and yielded two cuts, one boiling at 200-230°C. and containing 190 g., the second boiling at 178-186°C. weighing 63 g. The first fraction was again distilled and yielded a portion boiling at 213-215°C. which was said to be 2,2′-dimethyldicyclopentyl. The lower-boiling cut (from the first operation) was found to contain a mixture of hydrocarbons having the general formula $C_{18}H_{32}$, but the structure of these was not determined. The lower layer of the original reaction products contained all the aluminum salts together with 75 g. of unsaturated hydrocarbons which were reported to be formed by the polymerization of the cyclohexene arising from the loss of hydrogen chloride from monochlorocyclohexane.

The action of caustic soda upon chlorinated cycloparaffin results in the formation of a mixture of alcohols and unsaturated hydrocarbons. In one procedure, dichlorocyclohexane was treated with 30 per cent sodium hydroxide at a temperature of 200-230°C.[39] A mixture of chlorocyclohexanols and intermolecular condensation products formed by cracking (even at these temperatures) of the dichlorocyclohexane was secured. It was stated that the presence of copper catalysts serves to accelerate thermal decomposition. The sodium salts of carboxylic acids, the latter obtained from the oxidation of petroleum oils, may be utilized to interact with monochlorocyclohexane.[40] If the temperature is kept at 120-140°C., all the chlorine is eliminated by heating at 160-170°C. to furnish a liquid which is said to be efficient as a drying oil.

Aniline may be employed to substitute an amino group in a chloro derivative of cyclohexane. For example, it has been suggested that 2 moles of aniline be boiled with 1 mole of monochlorocyclohexane in the presence of copper as a contact agent.[41] On cooling and acidifying with hydrochloric acid, a precipitate of monocyclohexylaniline hydrogen chloride is secured.

FIG. 166.—Apparatus Employed for Photobromination of Cyclohexane. (B. J. Wood and E. K. Rideal)

A study of the reaction velocity of monochlorocyclohexane with sodium methoxide (CH_3ONa), pyridine and piperidine has been made by Tronov and Ladigina.[42] They state that the chlorocyclohexane reacts very energetically with the methoxide but less readily than the corresponding aliphatic halides with amines and potassium amides. In its reactivity towards amines, monochlorocyclohexane very greatly exceeds that exhibited by nuclear substituted aromatic halides such as monochlorobenzene. The investigators conclude that there is a similarity between the reactivity of the halogenated cyclohexanes and the tertiary alkyl halides. It is stated that in general chlorine in chlorocyclohexane is not replaced but removed mainly as hydrogen chloride with the production of cyclohexene. The latter compound then undergoes an addition reaction to form a derivative of cyclohexane.

Bromination. Bromine may be substituted in cyclohexane when the two compounds are heated to 110°C. in sealed tubes and exposed to diffused sunlight. Also, aluminum bromide may be added as an accelerator, but in this case the cyclohexane ring is converted into one of methylcyclopentane.[43]

The photochemical bromination of cyclohexane has been investigated to determine the dependence of the velocity constant upon various factors and to account for the inhibitory effect of oxygen.[44] The reaction vessel consisted of a glass cylinder connected through capillary tubes to reservoirs containing the bromine and cyclohexane. A pressure gage was employed to measure the extent of reaction, and a mercury lamp to energize the reactants. The light was passed through a vessel with plane parallel glass faces in which cold water was employed to remove the infra-red line. The remaining lines were then filtered through a saturated solution of potassium dichromate, to which neodymium magnesium nitrate had been added, to separate the yellow line. In this manner only the mercury green line was allowed to reach the reactants. The reaction rate was stated to be directly proportional to the light intensity and independent of the concentration of cyclohexane. Also, it was pointed out that the velocity of the reaction is reduced by the presence of oxygen and that this inhibitory effect is independent of the presence of the cyclohexane. The conclusion is drawn that not atoms but excited bromine molecules are the primary photoactive constituent. Further, that it is not these excited molecules but excited $C_6H_{12}Br_2$ molecules which are deactivated on collision with oxygen. The mechanism of the photobromination and inhibition by oxygen was accordingly described by the reactions:

$$\begin{array}{lll}
Br_2 & + h\nu & \longrightarrow & Br_2'^{a} \\
C_6H_{12} & + Br_2' & \longrightarrow & C_6H_{12}Br_2' \\
C_6H_{12}Br_2' & & \longrightarrow & C_6H_{11}Br' + HBr \\
C_6H_{12}Br_2' & + O_2 & \longrightarrow & C_6H_{12} + Br_2 + O_2 \\
C_6H_{11}Br' & + Br_2 & \longrightarrow & C_6H_{10}Br_2 + HBr
\end{array}$$

[a] Br' represents an activated bromine molecule.

On the other hand, Jost[45] pointed out that when reactions are carried out in the temperature range 78-106°C., the velocity constants are approximately proportional to the square root of the cyclohexane concentration. However, the velocity was said to be constant during any one experiment. The presence of hydrogen was reported to have no effect upon the speed of the substitution but oxygen greatly retards the reaction.[46] The quantum efficiency was stated to be about 2 at 20°C. and to increase with rising temperatures, being of the order of 12 to 40 between 73 and 100°C.

It is interesting to note that monobromocyclohexane may be prepared from cyclohexanol. In one process,[47] the alcohol is heated to 100-120°C. and dry hydrogen bromide passed in for 1.5 hours. As soon as replacement of the hydroxyl group is complete the products are separated to remove aqueous hydrobromic acid. Concentrated sulphuric acid is then incorporated in the bromide portion to convert any free alcohol to the acid sulphate, which is soluble in 50 per cent methyl alcohol and ammonia and may be removed by these reagents. The yield of monobromocyclohexane is said to be 75 per cent of the theoretical amount. Phosphorus tribromide has been recommended in place of hydrogen bromide for the preparation of monobromocyclohexane in certain instances.[48] Phosphorus tribromide and cyclohexanol in the molecular proportion 1:3 are mixed and allowed to stand at 20°C. for 12 hours. The resulting compounds are duly heated under a reflux condenser for 2 to 3 hours to form a separate aqueous layer containing phosphorous acid which may be removed. The remaining hydrocarbon bromide is then washed with concentrated sulphuric acid and distilled at 760 mm., the portion boiling at 165-166°C. being retained. Also it has been suggested that bromine and cyclohexanol be incorporated in a solvent of carbon tetrachloride to furnish dibromocyclohexane.[49] However in this case the yield is said to be relatively low since tetrabromocyclohexanone is always formed in the same proportion as the dibromide.

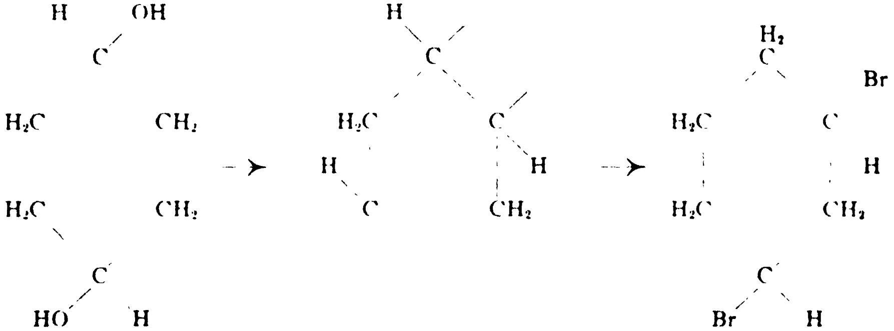
Compounds which contain two hydroxy groups have been utilized to furnish dibromo derivatives of cyclohexane. For example, Rothstein[50] reports that the action of concentrated hydrobromic acid upon 1,3- and 1,4-cyclohexanediol leads to the production of 1,3-dibromocyclohexane. The formation of the latter compound from the 1,4-cyclohexanediol is explained as a "pseudomigration," that is, a hydrogen atom and hydroxyl group split off from adjacent carbon atoms to form water, and that hydrogen bromide is then added to the double bond.



However, Zelinskii and Kozeshkov[51] maintained that the interaction of aqueous hydrobromic acid upon 1,4-cyclohexanediol caused substitution to take place in the 1 and 4 position with a resulting formation of 94 per cent of 1,4-dibromocyclohexane. These investigators stated that a small amount of a solid isomer, either 1,2- or 1,3-dibromocyclohexane, was also secured.

Dibromo derivatives of cyclohexane may be prepared from unsaturated cyclic compounds as for example cyclohexene.[52] Bromine dissolved in carbon tetrachloride is added to a cooled solution (0°C.) of cyclohexene in carbon tetrachloride, the rate of mixing being regulated so that the temperature will not rise above 3°C. When the reaction has been completed, carbon tetrachloride and excess cyclohexane are removed by distillation and the residue is fractionated. The reported yield of 1,2-dibromocyclohexane is 73-86 per cent of the theoretical amount.

Reactions of the Bromocyclohexanes. Among the reactions of the bromine derivatives of cyclohexane, the formation of a Grignard reagent through interaction with magnesium has received attention. Gilman and McCracken[53] investigated the reaction between monobromocyclohexane and magnesium to determine the yield of Grignard reagent that could be secured from this halide. Magnesium (1.25 g.) was introduced into a flask, and after all the air had been driven out by a stream of hydrogen gas, ether was then introduced. The mixture was stirred and a solution of 7.69 g. of cyclohexyl bromide in ether slowly incorporated over a period of 45 minutes. The amount of cyclohexyl magnesium bromide produced was stated to be 68.32 per cent of theoretical. One of the possible uses of the Grignard reagent is indicated by Hiers and Adams.[54] They combined magnesium and cyclohexyl bromide in the ratio 1 :1 by moles employing dry ether as a solvent. The Grignard compound was then reacted with methyl λ-aldehydododecanoate ($CHO-(CH_2)_{11}-COOCH_3$) and the product condensed to furnish μ-cyclohexyltridecanoic acid, which is said to be effective in killing *lepra* bacillus. Dihydrochaulmoogric acid, whose ethyl and sodium derivatives are stated to kill

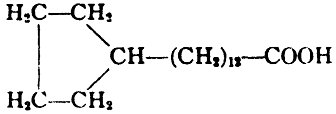
[53] H. Gilman and R. McCracken, *J.A.C.S.*, 1923, 45, 2462; *Chem. Abs.*, 1923, 17, 3859; *J.C.S.*, 1924, 126 (1), 23.

[54] G. S. Hiers and R. Adams, *J.A.C.S.*, 1926, 48, 1089; *Chem. Abs.*, 1926, 20, 1599; *Brit. Chem. Abs.* A, 1926, 597.

this bacillus, have the same straight chain as the acid mentioned above, but contain a cyclopentyl in place of the cyclohexyl ring.



The latter acid may be obtained from the natural chaulmoogra oils, which have been employed in treating leprosy.

Further, the preparation of Grignard reagents from difficultly soluble halides has been investigated. The addition of a small amount of ethyl bromide is said to aid the interaction between monobromocyclohexane and magnesium. Grignard[55] points out that the reason for the successful operation of the ethyl halide was the fact that it cleansed the magnesium and halides. Urion,[56] however, maintains that the main reason for the success of this method is that the ethyl bromide acts as a carrier, according to the equations:

$$C_2H_5Br + Mg \longrightarrow C_2H_5MgBr$$
$$C_2H_5MgBr + C_6H_{11}Br \longrightarrow C_2H_5Br + C_6H_{11}MgBr$$

To demonstrate this, 1 mole of ethyl bromide was treated with an excess of magnesium. The liquid was then decanted from the unreacted magnesium, and 1 mole of monobromocyclohexane added to the former. The two liquids were kept in contact for a period of 24 hours after which the mixture was hydrolyzed. A yield of 10 g. of cyclohexane, corresponding to a 12 per cent yield (by the second reaction above) was obtained. Distillation of 65 per cent of the ether solvent was said to raise the yield of cyclohexane to 40 per cent, since this substance carried off the ethyl bromide as quickly as it was formed.

The bromine derivatives of cyclohexane are utilized in the production of cyclohexylamines. For example, 1 mole of monobromocyclohexane was boiled with 2 moles of aniline in the presence of a copper catalyst.[57] When the solution had been cooled and acidified with hydrochloric acid, a precipitate of monocyclohexylaniline hydrogen chloride was formed. Certain other compounds containing nitrogen will also react with the bromides of cyclohexane. Thus, 1 part of 1,2-dibromocyclohexane is combined with 4 parts of quinoline at 237°C.; cyclo-1,3-hexadiene and 1-monobromocyclo-1-hexene are stated to be obtained.[58]

Potassium phthalimide ($C_6H_4(CO)_2NK$) and 1,4-dibromocyclohexane heated together at 160-165°C. for 8 hours yield 33 per cent of monobromocyclo-3-hexene, which may be isolated by steam distillation.[59] Semb and McElvain[60] have made a study of the reactivity of various normal, secondary and tertiary alkyl halides with piperidine as compared with that of monobromocyclohexane and the same nitrogen compound. They found that the normal or primary alkyl halides reacted completely with the naphthene base in 48 hours. The secondary and tertiary halides were much less disposed to react. Monobromocyclohexane, which may be considered as a secondary halide, is far less reactive than any of the three classes mentioned above. It was suggested, therefore, that the reactivity which the other secondary bromides show may be due to a rearrangement to the more reactive primary bromide, and that the non-reactivity of the cyclohexyl bromide may be attributed to its inability to undergo rearrangement. In a later work[61] it was reported that from *n*-, *iso*-, *sec*- and *ter*-butyl bromides and piperidine, four different N-butylpiperidines are formed. This fact was said to be a definite proof that these bromides interact with piperidine to give tertiary amines without rearrangement. A comparison of the behavior of *sec*-butyl bromide and cyclohexyl bromide upon admixture with piperidine is stated as an indication that the difference in reactivity of these secondary bromides is one of degree rather than kind.

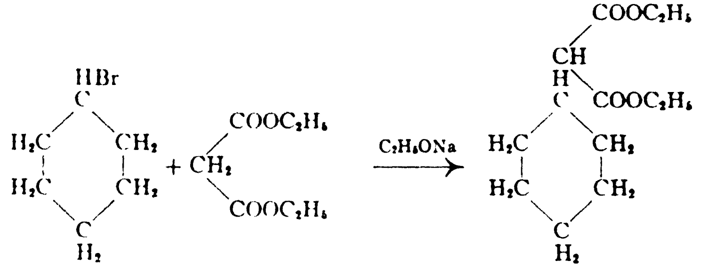
Also it is interesting to note that when monobromocyclohexane is heated under a reflux condenser for 24 hours with potassium carbonate in water, 8.3 per cent of cyclohexene is formed.[62]

The action of the sodium salts of malonic acid upon monobromocyclohexane leads to a number of products, among them ethyl cyclohexyl malonate.[63] To obtain the latter it has been recommended that sodium be dissolved in alcohol and the solution mixed with ethyl malonate and bromocyclohexane. The composite is then heated on a water bath for 24 hours. Water is incorporated and the product extracted with ether. The latter solution is washed, dried, evaporated, and the residue distilled under a pressure of 20 mm., the fraction boiling at 163-165°C. at this pressure being ethyl cyclohexyl malonate.



Fluorination. The fluorination of cyclohexane has not been reported, but the preparation of fluorinated derivatives by indirect methods has been described. For example, Swarts[64] suggests that monobromocyclohexane be heated with mercurous fluoride in a platinum or copper flask on an oil bath at 130°C. for a period of 5 days. The best yields of monofluorocyclohexane were obtained with the latter apparatus. Under these conditions, 30 per cent of the monofluoride was produced, together with 31 per cent of cyclohexene, 12 per cent of a polymerized product, and some of the original reactants. The use of platinum apparatus increased the amount of polymer to 26 per cent. The mixture of monofluorocyclohexane and cyclohexene was steam-distilled and the unsaturated cyclic hydrocarbon removed (from the distillate) as dibromocyclohexane by adding bromine in aqueous potassium bromide to the cyclohexene at 0°C., in the presence of diffused sunlight. To obtain purified monofluorocyclohexane the mixture was fractionally distilled under 100 mm. pressure, the portion boiling at 43.2°C. being retained. The fluorine derivative had the following properties: melting point, 13°C.; boiling point at 760 mm, 100.2°C.; d_4^{20} 0.9296; n_D^{20} 1.4146. A fluorine derivative boiling at 100°C. has also been secured from the interaction of cyclohexane and fluorine in a solution of difluorodichloromethane at —80°C.[65]

Properties of Fluorocyclohexane. Swarts[66] has found that monofluorocyclohexane is rather unstable, splitting off hydrogen fluoride to form cyclohexene. This decomposition is reported to be catalyzed by sulphuric acid and phosphorus pentoxide, and autocatalyzed by the hydrogen fluoride which is formed. When treated with sodium, monofluorocyclohexane gave a precipitate of sodium fluoride. Simultaneously, cyclohexene, cyclohexane and a trace of dicyclohexane were formed. All attempts to prepare a Grignard compound with magnesium and ether were said to be fruitless. Bromine in acetic acid reacted slowly with monofluorocyclohexane but it was stated that the hydrogen bromide liberated accelerated the elimination of hydrogen fluoride, so that the main portion of the products consisted of dibromocyclohexane, together with a trace of a bromofluorocyclohexane which boils at 80°C. under a pressure of 30 mm.

Iodination. Reaction between iodine and cyclohexene, giving rise to iodo derivatives of cyclohexane, has been reported. The reactants were mixed in toluene at 0°C. in the presence of actinic light, and various catalysts, including lead chloride and silver perchlorate, were incorporated.[67] The presence of these catalysts was said to increase the rate of reaction which was determined by titration of the free iodine with sodium thiosulphate. The increase in the velocity depends not only upon the presence of contact agents, but also upon the proportion of the latter,

[65] W. Bockemüller, *Ann.*, 1933, **506**, 20; *Chem Abs.*, 1934, **28**, 118; *Brit. Chem. Abs.* **A**, 1933, 1139.

since greater amounts caused a corresponding rise in the reaction rate. This was reported to indicate the effect is not purely catalytic, but that formation of intermediate mixed halogens also takes place.

HALOGENATION OF HOMOLOGUES OF CYCLOHEXANE

Methylcyclohexane. The direct chlorination (and bromination) of methylcyclohexane at 0°C. in the presence of diffused daylight leads to substitution on the tertiary carbon atom.[68] This seems to be the only halogen substituted product which can be obtained, but a number of halomethylcyclohexanes may be prepared from the corresponding alcohols or unsaturated cyclic compounds.

Methylcyclohexanol is sometimes employed as a reagent for the formation of chloro- and bromoethylcyclohexane. When hydrochloric acid is combined with 1,2-methylcyclohexanol, 1-chloro-2-methylcyclohexane is said to be secured. The product boils at 88°C. under 100 mm. pressure and has d_4^{20} 0.9788.[69] Also, it has been suggested that phosphorus pentachloride be employed instead of hydrochloric acid.[70] An explanation of the formation of the chlorides from the alcohols has been offered by Mailhe and Murat.[71] They consider that the first step in the reaction is a dehydration, resulting in the splitting off of a molecule of water followed by the addition of hydrogen chloride (from the hydrolysis of the pentachloride) to the unsaturated cyclic compounds.

Among the unsaturated cyclic hydrocarbons which have been used to prepare halogen compounds are included 4-bromo-1-methyl-1-cyclohexene and methylcyclohexene. The former substance, when reacted with fuming hydrobromic acid, is reported to yield 1,4-dibromo-1-methylcyclohexane.[71a] Methylcyclohexene, when treated with bromine, furnishes 1,2-dibromo-1-methylcyclohexane. When mixed with bromine to which was added 1 per cent of aluminum, the hydrogen atoms of the cyclic portion are said to be removed, and the product of the reaction consists of pentabromotoluene.[72]

Dimethylcyclohexane. The cyclic hydrocarbons generally employed to prepare the halogen derivatives of dimethylcyclohexane are dimethylcyclohexanol and dimethylcyclohexene. Auwers[73] pointed out that 4-chloro-1,4-dimethylcyclohexane may be obtained from the reaction between 1,4-dimethyl-4-cyclohexanol and phosphorus pentachloride. The product boils at 50-52°C. under a pressure of 14 mm. and has d_4^{20} 0.943. In the same manner, 2-chloro-1,2-dimethylcyclohexane may be secured from 1,2-dimethyl-2-cyclohexanol. The chloride boils at 122.5°C. at 760 mm. and has d_4^{20} 0.779. When 1,3-dimethylcyclohexene is combined with bromine or chlorine a dihalodimethylcyclohexane is formed.[74] The latter substance may be distilled with quinoline and the fraction boiling at 129-130°C. at 745 mm. is said to be 1,4-dimethyl-2,4-cyclohexadiene.

Trimethylcyclohexane. Of the cyclohexane homologues with nine carbon atoms, 1,2,4-trimethylcyclohexane has been isolated from petroleum.[75] Chlorination of this hydrocarbon in the vapor phase, employing dry reagents, resulted in a mixture of monochlorides and dichlorides, whose structures were not determined.

Menthane. Chlorination of menthane, or 1-methyl-4-isopropylcyclohexane, in the vapor phase gives rise to a liquid monochloride which boiled at 208-210°C. The constitution of this monochloride is unknown and its homogeneity doubtful. The bromination of menthane has been reported by Schoeller and Borgwardt.[76] They recommend that 21 g. of menthane and a small proportion of iodine be placed in a flask at 0°C. and 24 g. of bromine be slowly poured into the mixture. Hydrogen bromide is evolved, and when this evolution is complete, the remaining products may be washed with water and a solution of sodium carbonate. To isolate the monobrominated menthane, the mixture is distilled under 15 mm. pressure, and the portion boiling at 115-120°C. is retained.

Chapter 32

Halogenation of Benzene and Its Immediate Homologues

Although benzene and other aromatic hydrocarbons of a related character are not normally found in substantial proportions in straight-run petroleum distillates, except in rare instances, nevertheless the trend of the industry towards highly cracked products or "aromatized" stock renders some account of the behavior of at least a few of the lower members of the benzene series an appropriate part of the present text.

Benzene reacts with the halogens either by addition or substitution, but toluene and the higher homologues give substitution products almost exclusively. In the latter case, however, the halogens may enter the side chain or the aromatic nucleus, depending upon conditions. The most important factors influencing the position which the halogens will take are temperature, illumination, catalysts, and to some degree the concentration of the reacting substances. High temperatures and exposure to light promote replacement in the side chain, and low temperatures, absence of light, and the activity of halogen carriers (iodine, iron or aluminum halides) favor nuclear substitution.[1]

CHLORINATION OF BENZENE

Photochemical Chlorination. Smith, Noyes and Hart[2] report that the photochemical chlorination of benzene vapor proceeds by a short chain reaction. There are two simple ways in which the chlorine atoms might substitute in benzene,

$$\begin{aligned} Cl + C_6H_6 &\rightarrow C_6H_5Cl + H && (1)\\ Cl + C_6H_6 &\rightarrow C_6H_5 + HCl && (2) \end{aligned}$$

and these would be followed by either

$$\begin{aligned} H + Cl_2 &\rightarrow HCl + Cl, \text{ or} && (3)\\ C_6H_5 + Cl_2 &\rightarrow C_6H_5Cl + Cl && (4) \end{aligned}$$

Since both addition and substitution occur, according to the investigators, neither reaction 1 nor 2 can be logically excluded, though relatively little can be said concerning their probability. Another mechanism which may be postulated is

$$\begin{aligned} Cl_2 + h\nu &\rightarrow Cl + Cl && (5)\\ Cl + Cl_2 + C_6H_6 &\rightarrow C_6H_6Cl_3 && (6)\\ C_6H_6Cl_3 &\rightarrow C_6H_6Cl_2 + Cl && (7)\\ C_6H_6Cl_3 &\rightarrow C_6H_6 + Cl_2 + Cl && (8)\\ Cl + Cl &\rightarrow Cl_2 && (9) \end{aligned}$$

---

[1] The mechanism of the action of halogen carriers is discussed by Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., Inc., New York, 1934.

[2] H. P. Smith, W. A. Noyes, Jr., and E. J. Hart, *J.A.C.S.*, 1933, **55**, 4444; *Chem. Abs.*, 1934, **28**, 709; *Brit. Chem. Abs.* **A**, 1934, 40.

where $h\nu$ = quantum of energy. At the beginning of the reaction, the rate of decrease of pressure is found to be proportional to the square root of the light intensity, and to the separate pressures of the chlorine and benzene.

Luther and Goldberg[3] have stated that oxygen acts as a powerful inhibitor upon the photochemical chlorination of benzene. To overcome this difficulty Nozicka[4] employed anthraquinone together with activated carbon as catalysts in the preparation of chlorobenzene from chlorine and benzene in the presence of light.

FIG. 169.—Benzene Chlorinators.

Catalytic Chlorination. A chlorination catalyst (halogen carrier) will effect substitution rather than addition in benzene in the absence of light and at ordinary temperatures. For example, a mixture of silicon, antimony trichloride and lead may be employed to secure phenyl chloride.[5] If the chlorination is continued the para isomer will be obtained. With the reactants in the vapor phase and with oxygen present, Mares[6] suggests an aluminum compound with copper, iron or cerium, or, alternatively, a Deacon process catalyst (clay saturated with cupric chloride). The temperature is maintained between 200° and 400°C. Other

contact agents include copper with a promoter consisting of cobalt, nickel, manganese or chromium, deposited on pumice or silica gel.[7] According to Likhosherstov and Aldoshin[8] chlorination of benzene with the aid of dichloropentamethylenetetramine and a small proportion of potassium chloride takes place smoothly and may be represented by

$$(CH_2)_5N_4Cl_2 + 2KCl + 2C_6H_6 \longrightarrow 2C_6H_5Cl + 2KCl + (CH_2)_5N_4H_2$$

The procedure consists in dissolving a mixture of benzene and potassium chloride in acetone and adding powdered dichloropentamethylenetetramine in small portions. Since the reaction is exothermic, cooling may be necessary, especially if too great a proportion of the amine is employed. Vorozhtzov, Zilberman and Grigor'ev[9] state that the yield of polychloro derivatives of benzene will be reduced to a minimum if the chlorination is carried out in the liquid phase at 35°C. in a series of columns packed with glass and iron rings. On the other hand Krivonos[10] main-

Electrolytic Chlorination. Jeunehomme[11] reports that phenyl chloride may be obtained by electrolysis of a solution of benzene, chlorine and hydrogen chloride in methanol. The anode is composed of carbon, the cathode of bright platinum, and the final product other than the halide is hydrogen. In explanation, the same investigator[12] postulates two reactions which occur simultaneously. In one the benzene reacts with dissolved chlorine molecules, and in the other with chlorine atoms on the surface of the anode.

Thermal Chlorination. Space velocity, that is, the number of volumes of gas, at the reaction tube temperature, passing through the heated zone in a definite length of time (usually per minute), influences the thermal chlorination of benzene.[13] For a given space velocity there is a critical temperature below which the amount of chlorine unconsumed increases rapidly. Above a certain temperature pyrolysis sets in and carbon is deposited. In one process a vaporized mixture containing 22.4 per cent of monochlorobenzene and 77.6 per cent of polychlorobenzenes is passed through an electrically heated silica tube at 800°C. and at the rate of 175 g. per hour. Chlorine is introduced at the same time at a velocity of

9.5 l. per hour.[14] The time of contact is 29.5 seconds and the yield contains 2.8 per cent monochlorobenzene, 87.1 per cent polychlorobenzenes, 8.9 per cent chlorinated biphenyls and 1.2 per cent tarry matter. A method of halogenating benzene with chlorine in the presence of an oxide of zinc, ferric iron or manganese has been proposed.[14a] If the substitution is effected in the absence of water and at 40°C., *p*-dichlorobenzene is reported to be the main product. The advantage of the process is said to be that chlorine monoxide, formed from zinc oxide and chlorine, is the halogenating agent. Thus, the formation of hydrogen chloride is prevented since the products consist of the dichlorobenzene and water.

$$\begin{aligned} 2ZnO + 2Cl_2 &\longrightarrow Zn_2Cl_2O + Cl_2O \\ C_6H_6 + Cl_2O &\longrightarrow C_6H_4Cl_2 + H_2O \end{aligned}$$

Liquid-Phase Chlorination. The substitution of chlorine in benzene with the resulting formation of benzene hexachloride ($C_6H_6Cl_6$)[14b] may be accomplished by mixing the two reactants in an autoclave (Fig. 172) in the liquid phase at a temperature of —15°C. and a pressure of 4 atmospheres.[15] Also, it has been pointed out that benzene hexachloride may be secured from the chlorination of a mixed petroleum-coal distillate.[16] The fraction of the latter mixture which distills in the range 75-90°C. is treated with chlorine in the presence of a layer of water. During the halogenation the reaction vessel is kept in an ice-water bath to control the heat of the reaction.

Miscellaneous Chlorination. To prepare 1,2,4,5-tetrachlorobenzene, Mills[17] employs crude *o*-dichlorobenzene containing between 5 and 20 per cent of *p*-dichlorobenzene. The mixture is treated with chlorine at 20-30°C., giving a crystalline product. After filtration, the latter is washed with some of the original halide. Filtrate and washings are recovered and chlorinated to obtain a maximum yield.

SEPARATION OF CHLORINE DERIVATIVES OF BENZENE

To separate a mixture of mono- and polychlorobenzenes Buchheim[18] suggests that water be added to the composite to give an azeotropic[19] boiling point of 91°C. On distillation, the phenyl chloride will be found in the distillate and the polychloro compounds in the residue. Bennett[20] reports that sulphonyl chloride will react upon *o*-dichlorobenzene, forming *o*-sulphonylchlorobenzene, but will have no effect upon *p*-dichlorobenzene. Thus it may be employed to separate the ortho from the para compound. Addition of zinc dust during distillation of chlorinated hydrocarbons is said to prevent the formation of hydrogen chloride.[21]

USES OF CHLORINE DERIVATIVES OF BENZENE

Monochlorobenzene and polychlorobenzenes have found industrial application in the manufacture of sulphur black dyes,[22] phenols, *o*-dihydroxybenzene, aromatic amines, diaryl ethers and ketones. The properties of the chloro derivatives make them applicable, in some cases, as liquid dielectrics and transformer oils. Miscellaneous uses include the analysis of graphite greases, the separation of wax from hydrocarbon oil, the removal of carbon deposits from engine parts, dissolving paint and varnish, preserving wood, destroying insects, and as solvents for refrigerants.

PREPARATION OF PHENOLS

The hydrolysis of chlorobenzene by steam with the aid of catalysts has been investigated by various workers. Among the contact agents suggested are the oxides of aluminum, thorium, titanium, zirconium and tungsten as well as silica gel.[22a] Also the use of platinum, silver, copper oxide, copper, cuprous chloride and magnesium oxide has been described.[22b] Prahl[23] recommends iron-free fuller's earth with cuprous chloride as a promoter, the reaction taking place at 300-650°C. Rittler[24] advocates the use of acid-treated bleaching clays, e.g., Tonsil, Frankonite, fuller's earth or bentonite. The apparatus consists of a kettle heated by a steam coil and connected to a column containing the contact agent (see Fig. 173). From the catalyst bed the vapors are conducted to a condensing coil, where the phenol, unreacted monochlorobenzene and hydrogen chloride are condensed and returned to the kettle. The latter contains caustic soda to neutralize the hydrogen chloride.

In an analogous process[25] a dilute solution of lime is employed to neutralize hydrochloric acid and a fractionating column is placed between the boiler and catalyst bed, the object being to reflux the phenol and thus prevent its recirculation through the cycle. (See Fig. 174.) Other contact agents include aluminum oxide, cupric phosphate and zinc oxide,[26] Holmes' silica gel[27] (containing 10 per cent of copper),[28] silicon dioxide, magnesium chloride and cuprous chloride,[29] hydrated sodium copper silicate[30] and metallic copper.[31] In conducting the hydrolysis of chlorobenzene with sodium hydroxide at 300-400°C. in iron tubes,[32] the addition of 1 per cent or less of sodium oleate or stearate is said to prevent formation of a scale (Fe_3O_4) which is liable to break off and block the tubes.[33]

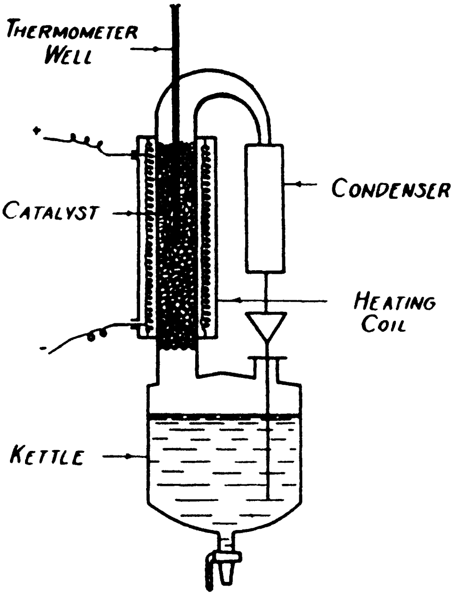

FIG. 173.
Catalytic Hydrolysis of Chlorobenzene to Phenol. (W. Kittler)

While investigating the possibility of preparing *p*-chlorophenol by action of alkalies on *p*-dichlorobenzene, Vorozhtzov and Karlash[34] noticed that phenol appeared as a by-product. It was thought that this reaction was caused by cuprous oxide (formed from metallic copper through the influence of alkalies) and that the reaction was

This hypothesis was substantiated when a 50 per cent yield of phenol was obtained by heating *p*-dichlorobenzene with cuprous oxide and water for 3 hours at 275°C.

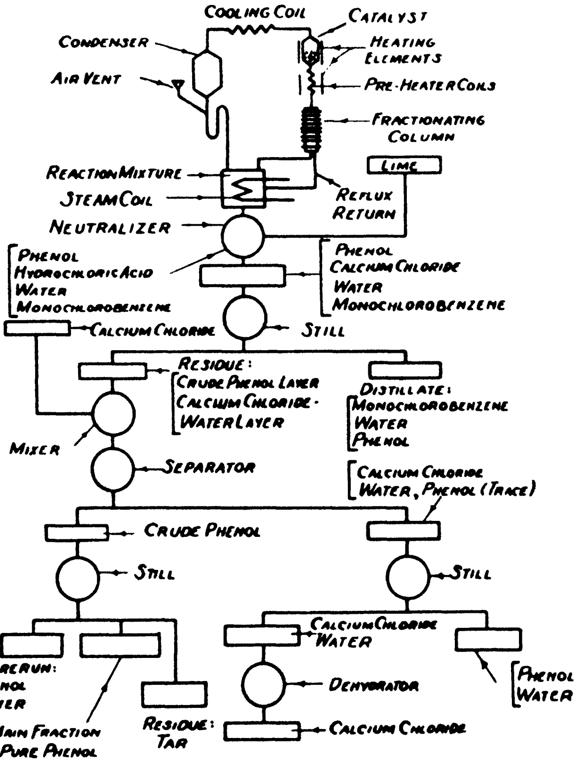

FIG. 174. Flow Chart for Hydrolysis of Chlorobenzene to Phenol. (R. L. Jenkins and J. F. Norris)

and under 80 atmospheres pressure. Similar treatment of *p*-chlorophenol at 250-380°C. also gives phenol.[35]

Preparation of Other Phenolic Substances. Hale[36] reports that the reaction of monochlorobenzene, sodium phenolate and free phenol under pressure at 350-420°C. results in the formation of phenylphenol (hydroxybiphenyl). Heating monochlorobenzene in an aqueous solution of sodium sulphide under pressure at 300°C. furnishes thiophenol.[37]

pheric pressure, and fresh stock simultaneously added, the process can be made semi-continuous.

PREPARATION OF ANILINE

Vorozhtzov[39] points out that the interaction of monochlorobenzene and aqueous ammonia with a cuprous salt as catalyst proceeds in two steps. In the first the halide reacts with the complex $Cu(NH_3)_2^+$ to form an addition product, according to the equation

$$C_6H_5Cl + Cu(NH_3)_2^+ \longrightarrow C_6H_5Cl \cdot Cu(NH_3)_2^+$$

In this compound the chlorine is very mobile and reacts rapidly with ammonia. yielding phenylamine,

$$C_6H_5Cl{-}{-}Cu(NH_3)_2^+ + NH_3 \longrightarrow C_6H_5NH_2 + HCl + Cu(NH_3)_2^+$$

The velocity of the first step is so much less than that of the second that the former alone determines the overall rate of reaction. The effect is to make the rate of consumption independent of the concentration of ammonia, as represented by

$$\frac{dx}{dt} = K(a-x)b$$

where $\frac{dx}{dt}$ is the rate of increase of product with respect to time, a is the initial concentration of phenyl chloride, x is the concentration of product at time t, b is the concentration of the catalyst and K is the reaction velocity. On the other hand, Groggins and Stirton[39a] maintain that the relation of ammonia concentration to amination and conversion for both catalytic and noncatalytic reactions is significantly altered by changes in temperature and ammonia liquor ratio. Also, they state that while for any particular ammonia concentration the rate of conversion is a function of the copper concentration, the anion accompanying the copper also exerts an influence on the reaction rate. With reference to the type of catalyst employed, Groggins and Stirton hold that:

1. Cupric and cuprous compounds are about equally active in the preparation of amines which are not readily susceptible to oxidation.
2. In the preparation of easily oxidizable amines, such as aniline, a low catalyst concentration results in a smaller difference in the reaction rates when cuprous and cupric compounds are compared.
3. The treatment of aniline with cupric nitrate leads to a much greater oxidation of amine than with cuprous chloride.

Vorozhtzov and Kobelev[40] report that phenylamine may be obtained by heating the corresponding chloride with concentrated ammonium hydroxide and cuprous oxide for two hours at a temperature of 250°C. and a pressure of 70 atmospheres. Hale[41] suggests the addition of some secondary and tertiary amines to the original material. The latter establish an equilibrium with the primary amine, and prevent the formation of more of the secondary and tertiary type. For vapor-phase reaction at 350°C. Prahl and Mathes[42] propose a promoter consisting of phosphoric acid and copper in silica gel. The use of an inorganic oxidizing salt to aid the reaction is recommended by Wuertz.[43] Potassium chlorate, ammonium nitrate and reduced copper may be used at temperatures of 160-220°C.

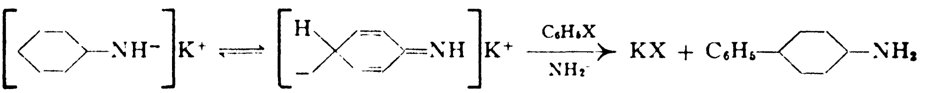
[42] W. Prahl and W. Mathes, U. S. P. 2,001,284, May 13, 1935, to F. Raschig G.m.b.H.; *Chem. Abs.*, 1935, **29**, 4382; *Brit. Chem. Abs.* **B**, 1936, 921.

The formation of phenylamine from monochlorobenzene has been studied to determine the course of the reaction and the rate of speed of substitution of the chlorine atom as compared to the other halogens.[44] It was stated that liquid ammonia solutions of potassium amide at —33°C. react very readily with monochloro-, monobromo- and monoiodobenzene to give aniline, diphenylamine, small quantities of *p*-aminobiphenyl and traces of triphenylamine. This may be represented as:

$$C_6H_5X + KNH_2 \longrightarrow C_6H_5NH_2 + KX$$
$$C_6H_5NH_2 + KNH_2 \longrightarrow C_6H_5NHK + NH_3$$
$$C_6H_5NH_2 + C_6H_5X \xrightarrow{NH_2^-} (C_6H_5)_2NH + NH_3$$
$$(C_6H_5)_2NH + KNH_2 \longrightarrow (C_6H_5)_2NK + NH_3$$
$$(C_6H_5)_2NK + C_6H_5X \xrightarrow{NH_2^-} (C_6H_5)_3N + KX$$



It was reported that the halogen group is removed almost quantitatively from monochlorobenzene by a liquid ammonia solution of an excess of potassium amide. However, when the halide is present in excess, potassium chloride is formed in yields of 50 to 60 per cent of the theoretical, as calculated from the first equation above. From this it was concluded that the second reaction, in which potassium anilide is produced, is more rapid than the first. Since the yield of halide ion is slightly greater than 50 per cent, calculated from the first and second equations, it was thought that potassium anilide and potassium diphenylamide must further react in the sense of the third, fifth and sixth equations. For these latter reactions the amide ion was said to be necessary as a catalyst.

Competitive experiments in which an ammonia solution of potassium amide was added to an excess of a mixture of aryl halides in the same solvent, indicated that bromine, iodine and chlorine, in that order, are replaced by potassium amide. Fluorine did not react under the conditions of the experiment.

The apparatus in which the reactions were effected consists of two Pyrex cells, both cooled by a liquid-ammonia bath. The cells are connected through a siphon so that solutions may be quantitatively transferred from the first to the second cell (see Fig. 176). Both cells are connected to a waste ammonia line and to a mercury bubbler. The latter is also joined to a gas collector. The potassium amide is incorporated in liquid ammonia in the first cell, and the entire contents are passed to the second reaction vessel. This contains a weighed amount of monochlorobenzene, delivered from a weight pipette.

Preparation of Other Amines. Treatment of 1,2-dichlorobenzene with ammonium hydroxide and reduced copper at a temperature of 150°C. and a pressure of 80 atmospheres will furnish 1,2-diaminobenzene.[45] The purpose of the copper is to form a complex with ammonia, as mentioned previously in the discussion of aniline.

Vogt[46] states that a phenol such as *m*-cresol may be heated with ammonia and hydrogen under 50-300 atmospheres pressure, employing hydrated alumina as a contact agent to give *m*-toluidine. Horsley[47] suggests ferric chloride as catalyst.

MISCELLANEOUS USES

Osterman[48] reported a method of preparing phenyl ether from phenol, potassium hydroxide and monochlorobenzene. The phenol is first combined with the hydroxide, and deprived of water:

$$C_6H_5OH + KOH \longrightarrow C_6H_5OK + H_2O$$

---

[46] E. Vogt, U. S. P. 2,013,873, Sept. 10, 1935, to General Aniline Works; *Chem. Abs.*, 1935, **29**, 6903.

[47] G. F. Horsley, U. S. P. 2,013,052, Sept. 3, 1935, to Imperial Chemical Industries Ltd.; *Chem. Abs.*, 1935, **29**, 6902.

[48] L. Osterman, U. S. P. 1,099,761, June 9, 1914; *Chem. Abs.*, 1914, **8**, 2779.

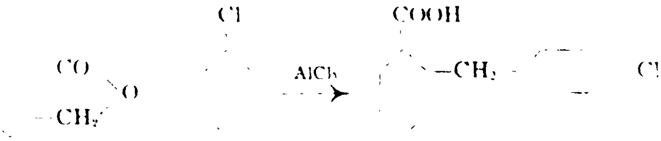
the dry phenolate is dissolved in phenol, mixed with monochlorobenzene and heated to 200-220°C., causing the formation of phenyl ether,

$$C_6H_5OK + C_6H_5Cl \longrightarrow C_6H_5OC_6H_5 + KCl$$

which is expelled from the reaction zone by steam and purified by distillation, the portion boiling at 115-116°C. under 7 mm. pressure being retained. Use of copper as catalyst and employment of temperatures of 300-340°C. have been proposed.[49]

To secure 4-chloroacetophenone, Groggins[50] condensed acetic anhydride with phenyl chloride by the Friedel-Crafts reaction using anhydrous aluminum chloride at a temperature of 100°C. The reaction was effected in a crystallizing pan equipped with a hermetically sealed cover, a modified plow for agitation of the charge, and a side door for discharging the reaction mass.

Jaeger and Daniels[51] point out that the same type of synthesis may be employed to furnish *p*-chlorobenzylbenzoic acid. The reactants are phthalide and chlorobenzene with anhydrous aluminum chloride, and their combination may be represented by



Clark[52] reports that some chlorohydrocarbons, particularly pentachlorobiphenyl and trichlorobenzene, are capable of serving as liquid dielectrics (e.g., as transformer oil). These are said to be oil-insoluble, stable, neutral and non-volatile. A mixture of the isomers of pentachlorobiphenyl has a pour point of 10°C. with no crystal formation, and a dielectric constant[53] of 5 at 25°C. The relatively high pour point of pentachlorobiphenyl would limit its use were it not for the fact that when mixed with trichlorobenzene it forms a composite having a pour point of —18°C. Although the latter is combustible under flash-producing conditions, it is said that the addition of 10 per cent of ethylene chloride will eliminate this undesirable property.[54]

In the analysis of commercial greases which contain graphite, it is often a matter of difficulty to separate such ether-insoluble materials as calcium stearate. Biffen[55] has proposed trichlorobenzene for this purpose; it is heated with the grease to 165°C., centrifuged and the halide decanted. Similarly a mixture of *o*-dichlorobenzene and either ethylene glycol or amyl alcohol is employed by McCarty and Skelton.[56]

Incorporation of 2 per cent of *o*-dichlorobenzene to mineral oil lubricants is said to reduce friction.[57]

Gerlach[58] recommends *o*-dichlorobenzene for removing carbon deposits from engine valves or pistons. The halide is mixed with triethanolamine and oleic acid and heated, with water, to 150-200°C. to form the cleaning bath. When mixed with kerosene and red oil, the dihalide is suggested as a cleansing agent for the water-circulating systems of automobiles.[59]

To secure a paint and varnish remover, propene dichloride and *o*-dichlorobenzene may be added to a lesser volume of acetone, carbon tetrachloride and benzene.[60]

Calcott and Foreman[61] use a 5 per cent solution of nitronaphthalene in *o*-dichlorobenzene to protect wood from fungus growth. The halide is employed as a solvent for methyl chloride in one absorption-type refrigerating apparatus.[62]

Both *o*- and *p*-dichlorobenzene have been suggested as insecticidal compositions. With the former, a mixture of the dihalide, ethyl alcohol, β-naphthol, rosin and a volatile petroleum solvent is used in termite control.[62a] In the extermination of moths, *p*-dichlorobenzene is said to be effective.[62b]

As a lubricant, a mixture of a lubricating oil and 1,2,4-trichlorobenzene has been proposed.[62c]

BROMINATION OF BENZENE

The bromination of benzene has not been reported in detail, but it would seem, in general, to resemble the chlorination of that hydrocarbon. Photochemical reaction using dry reagents results in addition products, while halogen carriers promote substitution.[63]

The activity of selenium and tellurium as carriers has been studied and contrasted with that of iron by O'Kelly.[64] In the reaction flask were placed 70.3 g. of benzene, 2 g. of iron and 0.5 g. of anhydrous aluminum chloride. Bromine was added until an excess of 80 per cent was present, and the mixture allowed to stand 12 hours at room temperature and an additional 7 hours with slight heating. Selenium, tellurium and a mixture of tellurium and iron were substituted singly in each of the succeeding runs. Results of the investigator have been compiled in Table 158.

Employment of such carriers as sulphur, iodine, antimony, bismuth and mercury in association with sulphonyl chloride with which the carriers are capable of oxidizing hydrogen bromide, has been proposed.[65] Normal temperatures and the

absence of light are utilized in the process, and tetra-, penta- and hexabromobenzenes are formed. Ferric chloride hexahydrate ($FeCl_3-6H_2O$), according to Menke,[66] or ferrous sulphate heptahydrate ($FeSO_4-7H_2O$) as well as the anhydrous salts are aids in the bromination of benzene. Addition of a nitrate or nitrite inhibits the activity of the catalysts. The employment of beryllium bromide as a catalyst for the bromination of benzene has been suggested.[67] With the reactants at 20°C., the products are said to contain mono-, di- and tribromobenzene.

FLUORINATION OF BENZENE

Fredenhagen and Cadenbach[68] have described a device which insures good distribution of fluorine in treating organic substances. It consists of a glass cylinder (externally cooled) which can be rotated about a horizontal axis. A copper tube with numerous fine openings along its length serves to introduce the fluorine. The latter is admixed with 15 volumes of nitrogen to serve as a diluent and to avoid inflammation. Interaction is enhanced by wrapping the tube in copper, silver or iron gauze. At 0°C., treatment of benzene furnished a product which contained 20 per cent of fluorine. Employment of fluorinated hydrocarbons, or other liquids

inert to fluorine, as diluents in this type of reaction has been proposed.[69] For example, the compound to be treated may be dissolved in liquid hydrogen fluoride, dichlorodifluoromethane, hexafluoroethane or trichlorotrifluoroethane and a catalyst such as iodine or antimony pentachloride added. In one example, 5 g. of benzene was admixed with 71 g. of anhydrous hydrogen fluoride in a copper vessel with an inlet tube of copper extending below the surface of the liquid (see Fig. 178). The reaction vessel was connected to a reflux condenser maintained at a temperature of —70°C. Fluorine was then conducted into the inlet tube until 5 g. had been absorbed. Hydrogen fluoride was then vaporized and the residue neutralized and extracted. In this manner a product containing 45 per cent of fluorine by weight was said to be secured.

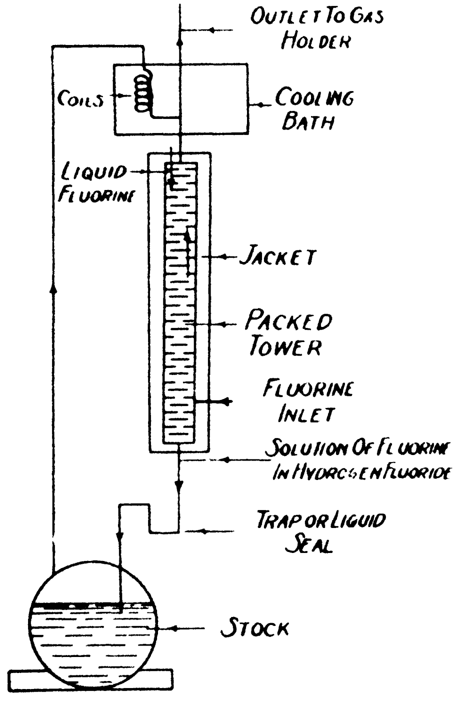

FIG. 178
Employment of Fluorine-containing Diluents in Fluorination of Organic Compounds. (E. I. du Pont de Nemours & Co.)

The fluorination of the chloro derivatives of benzene has received some attention. Daudt and Parmelee[70] point out that fluorochlorobenzenes may be procured by introducing fluorine above the surface of *o*-dichlorobenzene dissolved in trifluorotrichlorobenzene at —25°C. Bigelow and Pearson[71] report that the fluorination of hexachlorobenzene at 0°C. yields principally tetrafluorohexachlorocyclohexene ($C_6Cl_6F_4$, m.p. 113-114°C.) and some hexafluorohexachlorocyclohexane ($C_6Cl_6F_6$, m.p. 94-96°C.).

CHLORINATION OF TOLUENE

It was mentioned in the beginning of this chapter that toluene and its homologues undergo two types of substitution, nuclear and side chain. The factors influencing each substitution were also touched upon, and the conclusion stated that direct chlorination in the sunlight and at high temperatures promotes side chain reaction, while halogen carriers favor nuclear replacement.

Firth and Smith[72] have studied the chlorination of toluene and the effect of two catalysts upon the identity of the resulting halides. The contact agents employed were (a) activated charcoal and (b) iron-impregnated silica gel. The investigators point out that the former accelerates reaction and increases the amounts of side-chain substituents, and the latter induces nuclear substitution and condensation. Light was excluded and the temperature maintained at 110°C. throughout the chlorination. One hundred grams of toluene were employed in each run, and the results are shown in Table 159.

Nikolyuk[73] reports that if toluene is chlorinated in an iron apparatus with a chemically pure lead lining, the yield of benzyl chloride is 15.5 per cent (6.5 to 9.5 per cent over that obtained in glass-lined chambers). Commercial lead, on the other hand, brings about substitution primarily in the nucleus; even upon repeated chlorination the amount of benzyl chloride is small. Lead which has been used in a previous process is more active than that which is being used for the first time, but pretreatment with hydrochloric acid renders the lead less effective. Sulphur increases the amount of products obtained and partially prevents replacement in the nucleus. Alekseevskii and Krasavin[74] state that if a mixture of toluene, chlorine and hydrogen chloride is adsorbed by birch carbon or silicon dioxide and desorbed by steam at 120°C., mono- and dichlorotoluenes result. If aluminum oxide is present, trichlorotoluenes are predominant at the end of reaction.

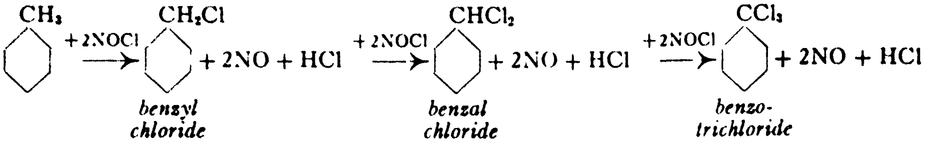
The action of nitrosyl chloride upon toluene has been investigated by Perrot[75] who points out that 2 moles of the halide unite with one of the hydrocarbon at 150°C. in sealed tubes to give benzyl chloride, benzal chloride and benzotrichloride.



The Uses of Chlorine Derivatives of Toluene

Benzyl chloride, like monochlorobenzene, may be hydrolyzed to yield phenolic compounds. For example, Hale[76] recommends that monochlorotoluene be heated in water to 300°C. with ammonia, cuprous oxide and calcium hydroxide to form a mixture of *o*- and *p*-cresol. According to Britton[77] no contact agent is needed for such a reaction if sodium rather than calcium hydroxide is employed. The interaction of higher chlorotoluenes with alcoholic potassium hydroxide at 140-210°C. may be utilized to produce chlorocresols.[78] However, Yamasaki and Titani[79] report that when the benzyl chloride is maintained in the vapor phase, it will not hydrolyze with water vapor after 5 hours heating at 130-200°C. nor with ethyl acetate after 150 hours at the same temperature.

Benzyl chloride may be heated with sodium acetate and acetic acid[80] or with acetic anhydride and bismuth oxide[81] to obtain benzyl acetate. Treatment of benzal chloride with aqueous sodium sulphite is said to result in the formation of benzaldehyde.[82] Also, it has been pointed out that the interaction of benzal chloride with dimethyl ether at 330°C. in the presence of alumina leads to benzene and methyl chloride.[82a] Benzotrichloride, according to Kranzlein and Hopff,[83] can be used in the preparation of naphthalene sulphonyl chloride. The method consists in heating the sodium salt of β-naphthalenesulphonic acid with the trichloride at 150-250°C. Kyrides[84] suggests that benzotrichloride be treated with phthalic anhydride at 200°C. to furnish phthalyl chloride. Zinc chloride may be employed as catalyst.

Cole[85] states that benzyl chloride, incorporated in a high-boiling distillate fraction of coal tar, serves as a corrosion inhibitor for metal surfaces.

Bromination of Toluene

The bromination of toluene is affected to a marked degree by the conditions of the reaction.[86] Temperature and light are two of the important factors in de-

termining the position of bromine in the resulting compound. If the halogen is added to cold toluene in the dark, the yield is mainly *o*- and *p*-bromotoluene. At a temperature of 100°C., however, in the absence of light-benzyl bromide is formed exclusively. Thus an increase in temperature favors side-chain substitution. In the presence of diffused daylight at 25°C., benzyl bromide is obtained and no nuclear substitution takes place. This would seem to indicate that the photochemical reaction has a greater effect on the position of bromine than the thermal reaction, provided the same temperature is employed in each case.

Nuclear substitution can be achieved by the activity of halogen carriers such as iodine, iron, antimony and aluminum bromides. In the presence of these substances, an excess of bromine furnishes polybromo derivatives. It is interesting to note that phosphorus pentabromide, unlike the other halides, favors side-chain rather than nuclear substitution.

The bromination of *o*-, *m*- and *p*-chlorotoluenes has been studied by Varma and Sahay.[87] Some of the results of their work are contained in Table 160.

TABLE 160.—*Bromination of Chlorotoluene.*

Chloride	Product	Boiling Point of Product
o-Chlorotoluene	2-Chloro-5-bromotoluene	90-3°C. (12 mm.)
m-Chlorotoluene	3-Chloro-4-bromotoluene 3-Chloro-6-bromotoluene	90-3°C. (12 mm.) 120-5°C. (15 mm.)
p-Chlorotoluene	*p*-Chlorobenzalbromide	

The halogenation of the higher homologues of benzene can occur in two ways, as in the case of toluene and benzene. Nuclear substitution may be brought about in the dark and at low temperatures, and by the use of halogen carriers. In the presence of actinic light or at high temperatures side-chain substitution takes place.

Chapter 33

Production of Alcohols by Hydrolysis of Alkyl Halides. Production of Esters

The alkyl halides, particularly the bromides and chlorides, are available for the manufacture of alcohols of the aliphatic series. Primary as well as secondary and tertiary alcohols may be prepared by the hydrolysis of the corresponding alkyl halide, distinguishing this process from the hydration of olefins, which yields only secondary and tertiary alcohols (ethanol, of course, being an exception).[1]

The hydrolysis of alkyl halides may be represented by the equation

$$C_nH_{(2n+1)}X \; + \; H_2O \;\rightleftharpoons\; C_nH_{(2n+1)}OH \; + \; HX$$

where X is a halogen but, in general, the point of equilibrium appears to rest on the left side, even at elevated temperatures. For this reason water alone (as liquid or vapor) is seldom used. Instead an alkali such as aqueous caustic soda, milk of lime or aqueous sodium carbonate is employed. The reaction is

$$C_nH_{(2n+1)}X \; + \; M'OH \;\rightleftharpoons\; C_nH_{(2n+1)}OH \; + \; M'X$$

where M′ is one atomic proportion of a monovalent element (or one-half atomic proportion of a divalent element).

Conversion of Methyl Chloride into Methanol

Methyl chloride can be converted to methanol in the liquid phase by using a solvent or in the vapor phase by passing the alkyl halide vapor and steam over heated solid hydroxides and condensing the alcohol vapors formed.[1a] Conducting the halide over calcium hydroxide, aluminum oxide or potassium hydroxide and at temperatures ranging from 300° to 350°C. has been suggested.[2]

Abkin and Medvedev[3] report the use of stannous phosphate deposited on pumice as a catalyst for vapor-phase hydrolysis of methyl chloride. At a temperature of 460°C. and with the ratio of steam to halide 10:1 (by volume) a 16 per cent yield of methanol was obtained. In the liquid phase the chloride may be heated in contact with aqueous alkaline solutions at temperatures of 150° to 190°C. and a pressure of 260 pounds per square inch. Dimethyl ether is also a product of the above reaction. To transform the ether to the alcohol, water and aluminum oxide may be added and the temperature maintained at 350°C.

$$(CH_3)_2O \; + \; H_2O \;\rightleftharpoons\; 2CH_3OH \quad -3 \text{ kg. cal.}^{3a}$$

Conversion of Halides of Ethane to Alcohols

Ethyl chloride reacts with the alkaline hydroxides, oxides and steam in a manner analogous to that for methyl chloride, forming ethanol. In the liquid phase, employment of aqueous potash or caustic soda and temperatures of 250-450°C. is recommended. In the vapor phase at 250°C. the use of a contact agent such as active charcoal impregnated with zinc sulphate is suggested. Diethyl ether is a by-product of both methods. To inhibit ether formation, Hale[4] suggests that

$$3C_2H_5Cl + 3NaOH \rightleftharpoons C_2H_5OH + (C_2H_5)_2O + 3NaCl + H_2O$$

a small proportion of the ether be added to establish an equilibrium with that secured from hydrolysis.

Klebanskii and Dolgopol'skii[5] point out that ethylene glycol $(CH_2OH)_2$ may be obtained by saponifying dichloroethane with sodium carbonate. When a mixture of 200 grams of the halide and 220 grams of the carbonate was heated to 175-195°C. at a pressure of 100 atmospheres, an 87-90 per cent yield of glycol resulted.

HYDROLYSIS OF HIGHER ALKYL HALIDES TO ALCOHOLS

Propyl Chloride. The hydrolysis of propyl halides has apparently received little attention. The work of Hughes[6] indicates that the conversion of isopropyl chloride to the corresponding alcohol (by treatment at 45°C. in 60 per cent of alcohol) is a unimolecular mechanism depending upon the ionization of the alkyl halide.

$$(CH_3)_2CHCl \rightleftharpoons (CH_3)_2CH^+ + Cl^- \text{ followed by}$$
$$(CH_3)_2CH^+ + OH^- \rightleftharpoons (CH_3)_2CHOH \text{ (instantaneously)}$$

The velocity constant[6a] of the reaction in a slightly alkaline medium is 2.60 and in an acid medium 2.58.

Butyl Chloride. Clarke and Cook[7] employ *n*-butyl chloride in preparing butyl alcohol. The halide is mixed with an aqueous suspension of ferrous hydroxide and the composite placed in an autoclave. A temperature of 75-150°C. and a pressure of 300 pounds per square inch are maintained for a period of 4 hours. The amount of alcohol may be increased by having present 1-2 per cent of pyrogallol (a reducing agent),[7a] which prevents the formation of aldehydes and acids.

Sparks and Nelson[8] report that the hydrolysis of 1,2-dichloro-2-methylpropane in the liquid phase at 70-80°C. leads mainly to 1-chloro-2-methyl-2-propanol, under neutral, slightly basic or slightly acidic conditions. The addition of basic substances to the hydrolysis mixtures tends to decrease the amount of alcohol furnished. Some of the results are shown in Table 161.

Saponification of 1,2,3-trichloro-2-methylpropane in dilute sodium hydroxide solution yields 3-chloro-2-methylallyl alcohol.[9] The reaction may be represented by

$$CH_2ClC(CH_3)ClCH_2Cl + 2NaOH \longrightarrow CHCl{=}CCH_3CH_2OH + 2NaCl + H_2O$$

The rate of conversion is directly proportional to the alkalinity of the reagent and

The mixed chlorides of isobutene may be treated, under superatmospheric pressures, with aqueous solutions of alkalies at temperatures above 100°C., best at 220°C. The products are isobutene, isobutyl alcohol and *ter*-butyl alcohol, which can be separated by fractional distillation.[9a]

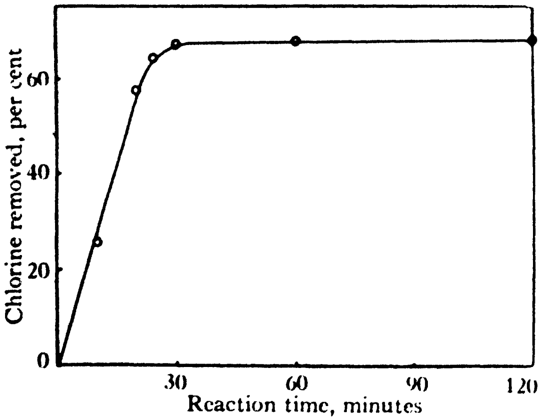

FIG. 179. Alkaline Hydrolysis of 1, 2, 3-Trichloro-2-Methylpropane. (A. O. Rogers and R. E. Nelson)

Courtesy Journal of American Chemical Society

Hughes[10] reports that the hydrolysis of *ter*-butyl chloride, like that of isopropyl chloride previously mentioned, is a unimolecular mechanism. The rate of reaction is dependent directly upon the velocity of ionization of the halide. When the latter is in excess, the speed of hydrolysis is constant and independent of the acidity or alkalinity of the medium. With a very dilute alcohol solution the velocity of reaction is also independent of the concentration of halide and water, but as the proportions of these latter increase, the rate of hydrolysis becomes more rapid. Woodburn and Whitmore[11] state that the speed of reaction is dependent upon the medium, being greater in pure water than in 5 per cent sodium carbonate solution. Some *ter*-butyl alcohol is formed when cold water is employed, but in hot water or in sodium carbonate solution olefins are obtained exclusively. A few results are listed in Table 163. Britton, Coleman and Warren[12] prepare *ter*-butyl alcohol by treating *ter*-butyl chloride with aqueous calcium hydroxide at 30-70°C. It is stated that any isobutyl chloride present will not undergo hydrolysis. To separate the alcohol from the unreacted chlorides, an azeotropic mixture of water, alcohol and chlorides is fractionally distilled. Fresh isobutyl chloride is added at intervals in quantities large enough to permit distillation of all the alcohol.[13]

Butyl Bromide. Investigation of the action of dilute aqueous solutions of inorganic bases on isobutyl bromide[14] has shown that the extent of reaction increases with a rise in temperature, being 40 per cent complete after 10 hours at 85°C. as compared to 12-13 per cent at 60°C. It was also found that the rate of hydrolysis increases with dilution of the reagents. If the concentration of base becomes greater or if the temperature is raised, there is a tendency to olefin formation. The latter is also affected by the cation of the base, the lowest yield resulting with silver hydroxide, the highest with caustic potash. The results of this experiment are illustrated by Table 164.

The hydrolysis of *sec*-butyl bromide in 60 per cent ethyl alcohol has been studied by Hughes.[15] He reports that the reaction has a unimolecular mechanism in dilute alkaline and dilute acid solution. As the medium becomes more alkaline there is a greater amount of olefin formation, and hydrolysis becomes a bimolecular reaction. In slightly alkaline solution the velocity constant is 2.52, in acid, 2.44. According to French, McShan and Johler,[16] alcohols are the chief products of the hydrolysis of *sec*- and *ter*-butyl bromides, though some olefins are also obtained. The action of a number of bases on these bromides is summarized in Table 165.

Amyl Chloride. The production of amyl alcohols and their acetates from chlorinated pentane has been conducted for a number of years.[17] A mixture of isomeric pentanes, obtained by fractional distillation of light petroleum, is chlorinated, heated under pressure with sodium oleate solution, and the amyl alcohols subsequently distilled off. This method yields all of the eight possible isomeric amyl alcohols. Campbell[18] reports the use of a semi-continuous process for the preparation of amyl alcohol from the corresponding chloride. The latter, with aqueous sodium hydroxide and amyl oleate (whose acid radical is a water-insoluble fatty acid) are placed in a reaction chamber and heated to 150°C. At intervals a portion of the liquid (containing oleic acid) is withdrawn from the bottom of the chamber, mixed with fresh chloride and alkali, heated and returned to the digester (see Fig. 181). In another method mono- and poly-chloropentanes may be treated with calcium hydroxide and sodium bicarbonate to furnish amyl alcohol.[19]

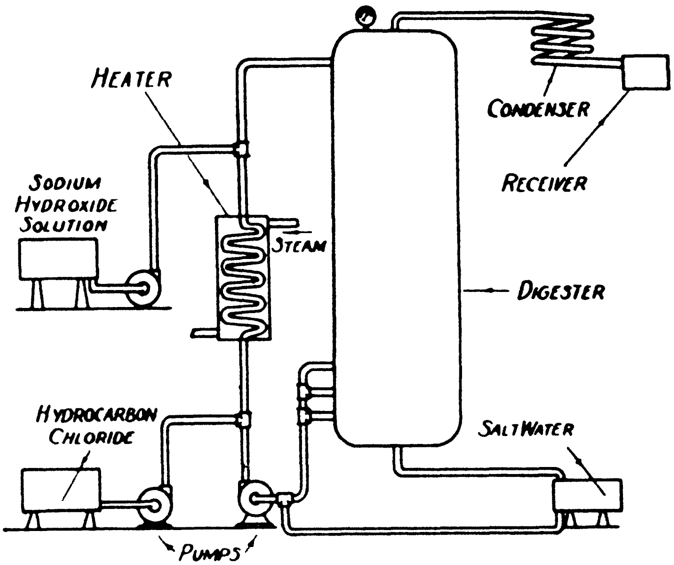

FIG. 181.—Semi-Continuous Method for Hydrolysis of Alkyl Halides. (C. L. Campbell)

When the temperature is maintained at 180-195°C., a 60 per cent conversion of halides in 40 to 60 minutes is reported. Clarke and Cook[20] suggest hydrolysis of the chloride with ferrous hydroxide at 75-150°C. to secure amyl alcohol. The optimum pressure is 300 pounds per square inch and the time of contact 4 hours. According to the above investigators a small amount of reducing agent (e.g., 1 per cent of pyrogallol) will inhibit aldehyde and acid formation. Ayres[21] recommends a method for separating products from reactants in the hydrolysis of chloropentanes. The products of the hydrolysis are said to be amylene (pentene), water, amyl chlorides (monochloropentane), higher boiling chlorides, and amyl alcohols. In the procedure these substances are placed in a flask heated by a steam coil.

The flask is connected through a rectifying column to a condenser which is, in turn, connected to a decanter and receivers (see Fig. 182). In the distillation the first compound which comes over is amylene, which may be seen from Fig. 183. An intermediate fraction containing amylene and amyl chloride is then taken off under reflux. As the temperature rises to 76°C. a constant boiling mixture of amyl chloride and water is removed. This mixture is conducted to the decanter where the water is separated and the halide returned to the distillation flask. If this step is effected without employing a reflux condenser, the removal of water is said to be facilitated, since a constant boiling mixture of amyl alcohol and water also comes over at this temperature. In this case, the chloride and alcohol are returned to the flask. Amyl chloride is next removed from the distilling flask by heating under a reflux condenser. The fraction which is secured is reported to contain some

amyl alcohol. At this point all the water and amyl chlorides are stated to be removed from the flask, but there still remains, in addition to amyl alcohol, some higher boiling chlorides. The latter are separated by adding 5 per cent of water to the residue in the still. In this manner a constant boiling mixture of the higher chlorides and water is taken off, leaving amyl alcohol as the residue.

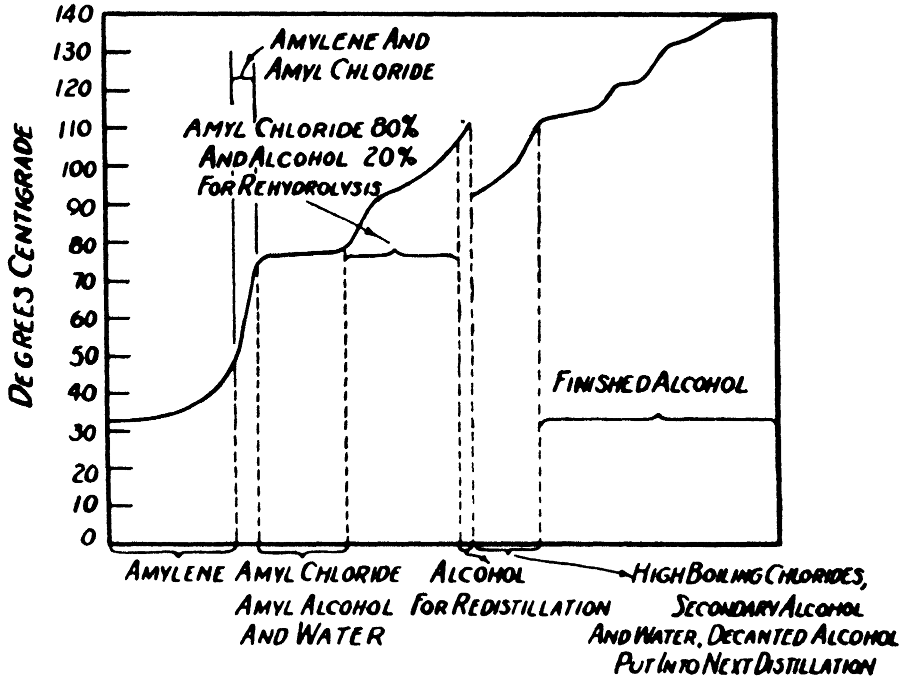

FIG. 183.—Typical Distillation Curve for Method of Fig. 182.

The action of various inorganic bases on *ter*-amyl chloride and bromide gives *ter*-amyl alcohol as the main product, together with some olefins.[22] The yield of the latter becomes greater with increasing temperatures and higher concentrations of hydroxide. The investigators also state that lithium, sodium and potassium hydroxide, in the order written, favor olefin production. Note Tables 166 and 167.

Chapter 34

Miscellaneous Reactions of Halogen Derivatives of Paraffins and Cycloparaffins

The chloro derivatives of the paraffin series are in general less reactive than the alkyl bromides and iodides, but this holds true only if the structure of the paraffin molecule is alike in the three halides. The primary substituted derivatives are less reactive than the secondary, but the tertiary undergo some reactions with remarkable ease. The latter halides, however, do not react with salts of organic acids or with alcoholic ammonia to form esters and amines, respectively, but instead are transformed, in part, to the corresponding olefin.

Because of the large number of alkyl halides[1] and the wide scope of their chemical reactivity, the following comments have been limited to include only some of the more interesting and important applications. Among these are:

(1) Production of olefins and hydrogen halides.[2]

$$C_nH_{(2n+1)}X \longrightarrow C_nH_{2n} + HX$$

(2) Condensation with alcoholic ammonia or with amines to yield alkylamines.

$$C_nH_{(2n+1)}X + NH_3 \longrightarrow C_nH_{(2n+1)}NH_2 + HX$$

(3) Condensation with hydrocarbons, or derivatives of hydrocarbons, under the influence of Friedel-Crafts condensing agents.

$$C_2H_{(2n+1)}X + C_6H_6 \xrightarrow{AlCl_3} C_nH_{(2n+1)}C_6H_5 + HX$$

(4) Reaction with sodium, potassium or ammonium sulphite to form sulphonates by what is called the Strecker reaction.

$$C_nH_{(2n+1)}X + Na_2SO_3 \longrightarrow C_nH_{(2n+1)}SO_3Na + NaX$$

(5) Replacement of halogen by acid radicals such as $-CN$ and $-SH$ through interaction with salts of these acids.

$$C_nH_{(2+1)}X + KCN \longrightarrow C_nH_{(2n+1)}CN + KX$$

(6) Interaction with metallic magnesium to yield Grignard compounds applicable in numerous syntheses.

$$C_nH_{(2n+1)}X + Mg \longrightarrow C_nH_{(2n+1)}MgX$$

(7) Reaction with alkali alcoholates or phenates to yield ethers.

$$C_nH_{(2n+1)}X + NaOR \longrightarrow C_nH_{(2n+1)}OR + NaX$$

Bell and Clark[3] have made a comparison of the preparation of unsaturated hydrocarbons from a number of halides by reaction with potassium hydroxide and with quinoline. The hydroxide, when united with *n*-halides, gave poor yields of olefins, possibly because of ether formation. On the other hand, good results were obtained with secondary, tertiary and cyclic halides. Quinoline was recommended for the preparation of unsaturated hydrocarbons from all normal halides and from secondary halides of low molecular weight. Under the same conditions of temperature and pressure, bromides and iodides furnish a greater proportion of olefins than do chlorides.

---

[1] For the number of mono- and di-substituted products, see Chapter 30.

[2] X represents an atom of chlorine or other halogen.

DECOMPOSITION OF ALKYL HALIDES INTO OLEFINS

The alkyl halides may be decomposed to yield olefins and hydrogen halides by the action of alkalies or alkali salts of organic acids as well as by heat with or without catalysts.[4] When alkalies are employed in aqueous or alcoholic solution, ethers and alcohols are produced in addition to the unsaturated hydrocarbons. Under the influence of heat, dechlorination is a reversible process in which the point of equilibrium of the equation $C_nH_{(2n+1)}X \rightleftarrows C_nH_{2n} + HX$ is displaced to the right with rising temperatures. Temperatures of 450-500°C. are required in order to remove chlorine from methyl chloride, but for the iodide the range may be restricted to 270-320°C.

When ethyl chloride is heated to 510-600°C. in the presence of pumice, ethylene is secured, the products of the reaction containing from 55 to 76 per cent of the unsaturated hydrocarbon. Yamaguchi[5] has made a study of some of the factors influencing the thermal dechlorination of tetrachlorethane. The use of activated carbon and of temperatures of 250-300°C. lead only to trichloroethylene. A temperature of 400°C. was necessary to produce ethylene. A small amount of ammonium hydroxide serves to accelerate the dechlorination, but ethyl alcohol has an inhibitory effect, as do the chlorides of nickel and barium. Aralkyl chlorides may also be employed as reactants to furnish unsaturated compounds. For example α-chloroethylbenzene may be treated with benzoic acid to obtain phenylethylene (styrene) and hydrochloric acid.[6] Evolution of hydrogen chloride begins at 130-140°C., the optimum temperature range being 150-200°C. The styrene is distilled from the reaction zone as quickly as it is formed, thus separating it from any unreacted chloroethylbenzene. The distillate is washed with sodium carbonate and fractionated, the portion boiling at 146°C. being retained. The unsaturated compound tends to polymerize[7] but this change can be prevented by having present a small proportion of nitrobenzene. According to Olivier and Weber[8] the bromides of ethane, on hydrolysis, will furnish ethylene. In one case 300 cc. of either 1,2-dibromoethane or ethylidene bromide were dissolved in 900 cc. of water and 300 cc. of acetic anhydride. A small amount (1 per cent) of 0.375 molar sulphuric acid was added and the temperature maintained at 60°C.

Senderens[9] points out that propyl chloride will not undergo dechlorination by heating to 140-280°C. unless a contact agent is present. Among those recommended are aluminum oxide at 280°C., thorium oxide at 260°C., zirconium oxide at 250°C., hydrous aluminum silicate (kaolin) at 230°C., calcium phosphate at

[9] J. B. Senderens, *Compt. rend.*, 1935, **200**, 612; *Brit. Chem. Abs.* **A**, 1935, 1064; *Chem. Abs.*, 1935, **29**, 2874.

260°C., anhydrous barium chloride at 270°C., and anhydrous calcium chloride at 265°C. These catalysts have also been found to aid the transformation of 1-chlorobutane to 1-butene and hydrogen chloride. However, in the case of 2-chlorobutane the dimethylethylene which results will recombine with the hydrogen chloride unless the two are separated rapidly, which may be accomplished by fractionation. Calcium oxide may also be used as a promoter in the dechlorination of butyl chloride.[10] Formation of butene begins at 275°C. but the optimum temperature is 285°C. The contact agent reacts with the resulting hydrogen chloride to form calcium chloride. The latter is said to catalyze the reaction so that the temperature may then be reduced to 225°C. without affecting the yield of olefins. Dechlorination of *ter*-butyl chloride has been accomplished without the aid of promoters.[11] The reaction was conducted in a flask coated on the inside with carbon, and the temperature was varied for different runs between 547-645°K. (820-918°C.). The reaction is reported to be homogeneous and unimolecular with an energy of activation of 45,000 ± 1900 cal.

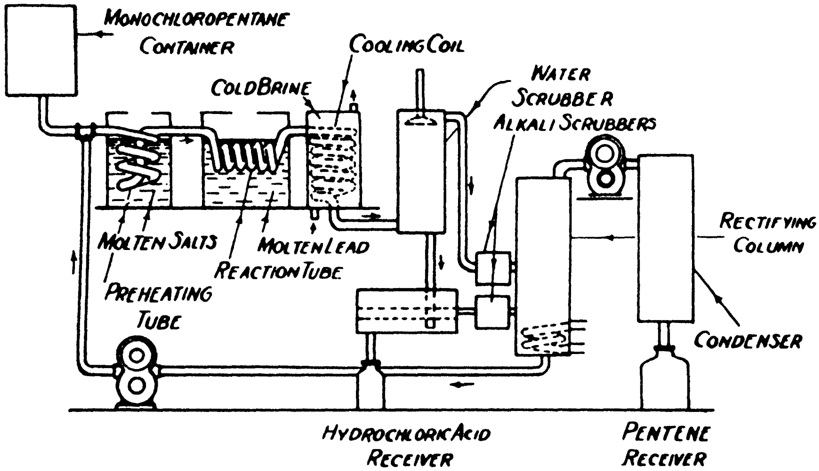

FIG. 184.—Sketch of Equipment for Production of Olefins from Alkyl Halides. (H. B. Hass and P. E. Weston)

Although the bromides of butane furnish olefins more readily than do the chlorides, there is an almost immediate recombination of the reaction products so that separation of the latter is rather difficult. This has been noted by Senderens[12] when forming dimethylethylene and hydrogen bromide by heating isobutyl bromide with thorium oxide at 200°C. and butyl bromide with the oxides of aluminum and thorium at 280-300°C.

Hass and Weston[13] point out that the dehalogenation of a mixture of 2-bromo and 3-bromopentane may be utilized to prepare 1-pentene and 2-pentene. The halides are led through a preheating tube where they are vaporized (see Fig. 184). The vapors are then conducted into a reaction chamber, heated to 500°C. by a bath of molten lead. After a contact period of 1.5-2 seconds, the reaction products are cooled to 20°C., washed with water, and fractionated to separate the pentenes from hydrobromic acid and unreacted halides. The latter may then be recycled. Thermal decomposition of *ter*-amyl chloride at 543-600°K. (816-873°C.) is said to follow a unimolecular, homogeneous reaction having an activation energy of 46,200 ± 700 cal.[14]

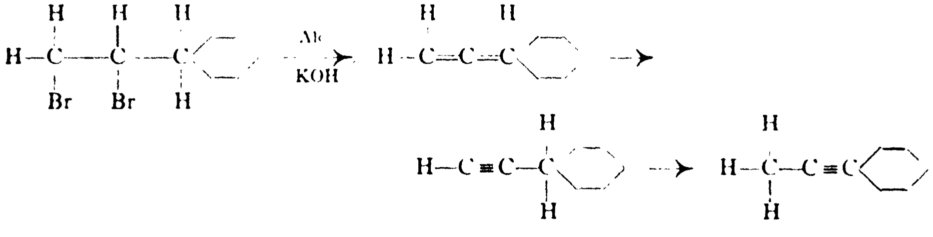
Monochlorinated paraffins containing more than 8 carbon atoms are reported to give olefins and diolefins on dehalogenation. Ward and Fulweiler[15] point out that at 180°C. potassium cresolate reacts with chloro-2,7-dimethyloctane to furnish decene. A yield of 91.6 per cent of an olefin boiling between 159.6 and 162.8°C. was obtained which would correspond to 2,7-dimethyloctene (boiling between 159-162°C.) secured by Kishner.[16] Also, it has been suggested that dehalogenation of a chlorinated kerosene fraction (b.p. 243-258°C.) may be effected to yield unsaturated aliphatic hydrocarbons.[16a] Thermal treatment of polychlorinated paraffin hydrocarbons is said to form products applicable as lubricants.[17] For example, a paraffin containing 42 per cent of chlorine was heated to 300°C. yielding a product having a high viscosity and flash point and a low melting point (−20°C.).

Substances capable of reacting with hydrogen chloride may be employed in dehalogenation. For example, reaction of 1,2,3,4-tetrachlorobutane with potassium hydroxide in methyl alcohol at 10° to 18°C. is said to yield butadiene.[18]

Aralkyl dihalides have also been dehalogenated. According to Zeberg[19] solid potassium hydroxide caused dehalogenation of 1,2-dibromo-3-phenylpropane at a temperature of 110°C. with alcohol as a solvent. Phenylallene was first formed and then underwent isomerization first to benzylacetylene and later to methylphenylacetylene.



An interesting sidelight on dehalogenation has been noted by Sandonnini and Borghello.[20] Electrolysis of carbon tetrachloride in a 10 per cent sulphuric acid solution, employing a platinum anode and a lead cathode, gave chloroform (trichloromethane) and dichloromethane rather than olefins.

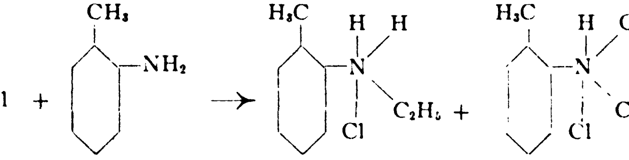
REACTION OF CHLORINATED PARAFFINS AND CYCLOPARAFFINS WITH AMMONIA AND AMINES

The primary and secondary alkyl halides react with ammonia and amines to form alkylamines, whereas the tertiary halides yield only olefins on similar treatment. The condensation usually takes place in alcoholic solutions with moderate heating (100°C.) and primary, secondary and tertiary amines result as well as quaternary compounds in some cases.[21] The ammonolysis of ethyl chloride may be represented by

$$\begin{array}{l} C_2H_5Cl + NH_3 \rightarrow C_2H_5NH_2 + HCl \\ C_2H_5Cl + C_2H_5NH_2 \rightarrow (C_2H_5)_2NH + HCl \\ C_2H_5Cl + (C_2H_5)_2NH \rightarrow (C_2H_5)_3N + HCl \\ C_2H_5Cl + (C_2H_5)_3N \rightarrow (C_2H_5)_4NCl \end{array}$$

Tolmachev[22] reports that the reaction of ethyl chloride with an aromatic compound such as *o*-toluidine leads to ethyl *o*-tolyl and diethyl *o*-tolyl ammonium chloride according to the equation:



If an autoclave is employed in which temperatures of 170-200°C. are maintained, the yields are independent of an excess of halide or of the length of heating time. With molar quantities of reactants 70 mole per cent of the ethyl and 15 mole per cent of the diethyl compound are formed. According to Carleton and Woodward,[23] ethyl chloride will form a secondary and tertiary amine with aniline if the two are reacted in ethanol solution. Thus, 465 g. of aniline, 208 g. of ethyl chloride and 250 g. of ethanol were heated for 5 hours at 180-185°C. under a pressure of 175-225 lbs. per square inch. At the end of the contact period, the mixture was made alkaline and the oil layer separated. The latter was stated to consist of 60 per cent of monoethylaniline and 40 per cent of diethylaniline. The chloride will also undergo condensation with α-naphthylamine if solvents are excluded from the reaction zone.[24] The temperature should not exceed 155°C. during the reaction, and in the final stages should be lowered to 140°C. The products of the ammonolysis include ethyl-α-naphthylamine.

To prepare ethylenediamine, Curme and Lommen[25] suggest treatment of dichloroethane with excess aqueous ammonia at a temperature of 110°C. and a pressure of 10 atmospheres. The reactants are conducted into a pressure-tight reaction vessel where they are admixed under the conditions mentioned above. A portion of the reaction products, reported to consist of an aqueous solution of ethylenediamine hydrochloride, ammonium chloride and ammonia, is withdrawn intermittently from the reaction zone (see Fig. 185). The mixture is then conducted to a fractionating column where it is heated with aqueous caustic soda. In this manner ethylenediamine is said to be formed and ammonia released from the ammonium halide. The ammonia is returned to the reaction vessel and the diamine drawn off.

Ethlylenediamine is reported to be effective as a solvent for certain vat dyes, as a stabilizer for latex and as a corrosion inhibitor.[27] It has also been recommended for maintaining the color of mineral lubricating oils during refining of the latter.[27a] For this purpose 0.1-0.005 per cent of the diamine is said to be sufficient. The higher fatty acid soaps such as oleyl ethylene diamine are suggested as detergents for use in acid solutions.[28] Caspe[29] proposes to use diethylamine as a reactant in the manufacture of tertiary amines. In this procedure 1 mole of isopropyl bromide, 1 mole of diethylamine and 0.5 mole of glycerol are heated

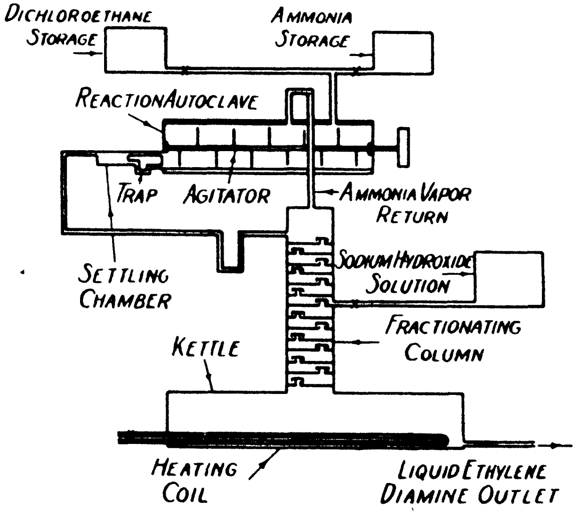

FIG. 185. Formation of Ethylene Diamine from Dichloroethane. (G. O. Curme, Jr., and F. W. Lommen)

under a reflux condenser for several days. The composite is then made alkaline with sodium hydroxide, extracted with ether, and distilled to secure the fraction boiling between 108 and 109°C. which contains diethylisopropylamine.

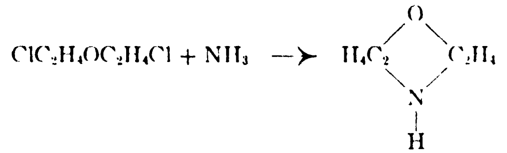
One method for the preparation of morpholine is by reaction of *sym*-dichlorodiethyl ether and ammonia.[30] The reaction zone consists of an autoclave in which a temperature of 50°C. and a pressure of 1750 pounds per square inch are maintained. The condensation may be represented by the equation,



The product is said to be efficacious as a solvent for dyes, a corrosion inhibitor for water solutions, a color stabilizer for petroleum products, an antiknock agent for gasoline, and a carbon remover for aluminum pistons.[31]

Olin[32] reports that the product obtained by chlorinating a mixture of pentanes will yield mono- and diamylamines if reacted with an excess of ammonia. The amyl chlorides (1065 g.) and ammonia (680 g.) are dissolved in anhydrous ethanol. The temperature is maintained at 100-110°C. for 5 hours. Then the mixture is cooled to 20°C. and the solvent and excess ammonia distilled, leaving a residue of amyl ammonium chloride. Steam is introduced and caustic soda added to separate the amines from hydrogen chloride and unreacted amyl chloride. Two layers form, the upper containing the amines which may be fractionated to separate the mono- and diamylamines, the former boiling between 85 and 110°C., the latter above 110°C.

The halides of the higher members of the paraffin series may also be used to form primary and secondary amines. In one process octadecyl chloride is incorporated with 60-65 per cent ammonium hydroxide and the mixture heated in a closed vessel for 5 hours at 120-170°C.[33] According to Pyman and Levene[34] a secondary amine is obtained by heating 1,10-dichlorodecane with diamylamine, $(C_2H_5)_2NH$. The product, 1,10-bis(diamylino)decane, is said to be efficient in destroying microscopic organisms such as the amoeba. Also, it has been proposed[35] that a dichlorinated paraffin oil boiling about 150°C. be condensed with ammonia (in ethyl alcohol) at 160-170°C. The viscous oil which results is suggested as an acid soap in dyeing.

Wright and Bergstrom[36] point out that potassium amide reacts with an excess of phenyl chloride, bromide or iodide to give aniline, diphenylamine and a small proportion of triphenylamine. The condensation takes place in a liquid ammonia solution at −33°C.

CONDENSATION AND ALKYLATION BY MEANS OF ALKYL HALIDES

Under certain conditions the alkyl halides may be polymerized or may be employed to form condensation products or to introduce alkyl groups into aromatic compounds. In the latter case, benzene, toluene, naphthalene and the phenols comprise the general aromatic groups. The condensing agent usually employed is anhydrous aluminum chloride, though certain other chlorides are also effective. Some of the generalities regarding the Friedel-Crafts syntheses, as these reactions are called,[37] are summarized by Calloway[38] as follows:

1. Alkylation by means of this synthesis is a reversible reaction applicable to practically all types of organic compounds.
2. Acylations are essentially nonreversible and may be applied to a variety of reactants.
3. Rearrangements are prevalent in alkylation but acylation proceeds without rearrangement.
4. The orientation of entering groups is essentially that found in other substitution reactions.
5. A variety of condensing agents may be used, but aluminum chloride is apparently the most active.
6. The Friedel-Crafts reaction is catalytic, and there is apparently no formation of intermediate organoaluminum substances.

Prins and Englehard[39] reported that trichloromethane (chloroform) reacted with dichloroethylene ($C_2H_2Cl_2$) in the presence of anhydrous aluminum chloride to form 1,1,2,3,3-pentachloropropane according to the equation:

$$C_2H_2Cl_2 + CHCl_3 \xrightarrow{AlCl_3} CHCl_2CHClCHCl_2$$

The chloroform and olefin halide were separately heated for a few minutes with 1 per cent of the condensing agent and cooled. A mixture of 120 g. of the chloroform and 97 g. of dichloroethylene was then saturated with the aluminum halide and heated to 50°C. for 2 hours, giving a yield of 70 per cent of the pentahalide. It was pointed out that a number of high-boiling condensation products also result. The latter react with the dissolved aluminum chloride, rendering the catalyst inactive. Treatment of dichlorofluoromethane with a Friedel-Crafts condensing agent at 8 to 25°C. and at atmospheric pressure leads to difluorochloromethane and chloroform.[40] At 45°C. and at the same pressure, trichlorofluoromethane furnishes dichlorodifluoromethane and tetrachloromethane. In both cases a fluorine atom on one molecule is substituted for a chlorine atom on another molecule.

It has been proposed that dichloroethane be condensed with vinyl chloride in the presence of aluminum chloride.[40a] When the temperature is maintained below 60°C. the product is stated to be trichlorobutane. Under similar conditions, dichloroethane combines with *sym*-dichloroethylene to yield tetrachlorobutane, and with trichloroethylene to furnish pentachlorobutane.

Prins[41] noted that aluminum chloride can also be utilized to prepare hexachloropropene from pentachloroethane. With 1.5 per cent of condensing agent a temperature of 100-110°C. was maintained for 1.5 hours to give a 95 per cent yield of tetrachloroethylene. The latter was boiled for 10 minutes with 1.5 molecular equivalents of trichloromethane to form heptachloropropane in 85 per cent yield. This product was heated with tetrachloromethane and aluminum chloride at 60-70°C. to secure hexachloropropene. The three steps of the synthesis are summarized by the equations,

$$\begin{aligned} C_2HCl_5 &\longrightarrow C_2Cl_4 + HCl \\ C_2Cl_4 + CHCl_3 &\longrightarrow CHCl(CCl_3)_2 \\ CHCl(CCl_3)_2 + CCl_4 &\longrightarrow CCl_3CCl{=}CCl_2 \end{aligned}$$

A process in which a lubricating oil is treated with amyl chloride and a small amount of the chloride of aluminum has been proposed.[42] A contact time of 2 hours at 80°C. is said to increase the refractive index and reduce the amount of carbon residue in the oil. For example, 100 volumes of lubricating oil were admixed with 10 per cent of aluminum chloride and with 30 volumes of amyl chloride. The temperature was maintained at 175°F. (79°C.) for 2 hours. At the end of that time the mixture was conducted to a sludge separator where the aluminum chloride was removed (see Fig. 186). The oil may then be "sweetened" with sulphuric acid and clay or by steam to produce the finished oil. A composition said to be efficient as a dielectric may be obtained by polymerization of halogenated paraffins.[43] In one instance 1,2,2-trichloroethane is heated to 85°C. with 0.1-0.5

mole of aluminum chloride. The product is mixed with phenyl chloride to furnish a liquid having a melting point of —45°C. According to Austin[44] a *sec*-alkyl resorcinol may be secured from resorcinol and 1-chloro-2-methylheptane. The contact agent employed is zinc chloride and the temperature is maintained at 130°C. Koch[45] suggests that chlorinated paraffins boiling above 200°C. and from which the solid material has been removed be polymerized by heating to 130°C. in the presence of a Friedel-Crafts agent to furnish a synthetic lubricating oil. Also, it has been proposed that cracking and condensation of halogenated high-boiling oils be effected in the presence of aluminum which has been activated by treatment with mercuric chloride and hydrogen chloride.[46] In one instance, chlorine was conducted into a vessel containing a paraffin oil, the latter boiling above 350°C. (see Fig. 187). The reaction was begun at 20°C. and allowed to continue until an increase in weight of the oil of about 65 per cent had taken place. It was reported that the temperature rose to 100°C. at this point and that hydrogen chloride was split off. The halide was then admixed with an equal weight of an untreated gas oil boiling between 270 and 350°C. Nitrogen was incorporated as a diluent and the mixture led through a vessel containing the catalyst. During this step

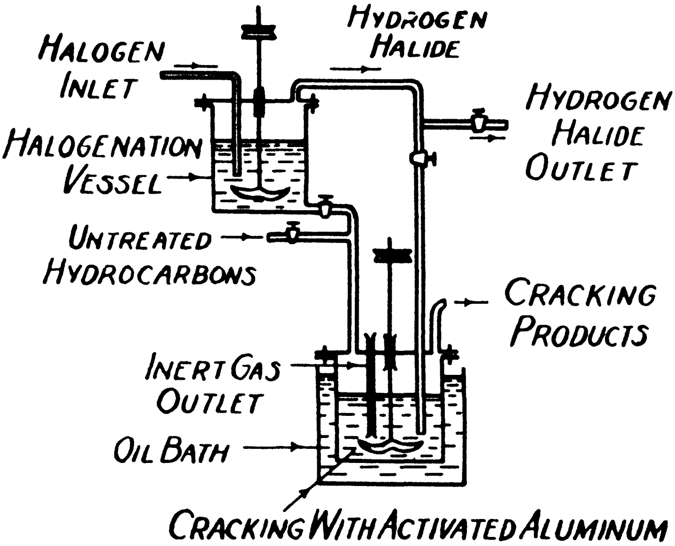

FIG. 187.—Halogenation and Cracking of High-Boiling Hydrocarbon Oils. (H. Engel and J. Jannek)

the temperature was maintained at 250°C. by means of an oil bath. In this manner, an oil was said to be secured, 40 per cent of which boiled below 200°C. and 15 per cent below 270°C. Fischer, Koch and Wiedeking[47] point out that polymerization of dichlorinated Kogasin[48] in the presence of aluminum chloride at 120°C. gives a synthetic oil which is said to have a high refractive index and to be resistant to oxidation. Resins may also be secured from petroleum distillates by this method. Fulton and Kunc[49] state that a petroleum distillate boiling between 150 and 350°C. under a pressure of 1 mm., may be chlorinated[50] and subjected to the action of a metal halide condensing agent. Thus, 1000 pounds of a distillate such as that mentioned above were chlorinated at 80°F. (26.6°C.). A cooling system was employed to maintain the temperature at that point until the chlorine content became 9.7 per cent by weight. The chlorinated products were then conducted into a vessel equipped with a reflux condenser and an agitator. There the halide was admixed with 50 pounds of anhydrous aluminum chloride and heated for 12 hours at 80-90°F. (26.6-32.3°C.). At the end of the heating period the products were washed and distilled. The highest boiling fraction was said to contain 293 pounds of a highly condensed product, which boiled off at 600°F. (315.5°C.) at 1 mm. The latter was ground and then extracted with 300 gallons

[50] The chlorination of petroleum hydrocarbons is described in Chapters 30 and 32.

Ulich and Heyne[52] have made a study of the kinetics of the reaction between benzene and propyl chloride in carbon disulphide solution. Chlorides of gallium and aluminum were employed as catalysts and the extent of alkylation was determined by measuring volumetrically the amount of hydrogen chloride evolved. It was found that with the first-mentioned contact agent the substitution of the propyl group proceeds by the formation of an intermediate, gallium chloride-propyl chloride complex. The latter is in equilibrium with the remainder of the condensing agent, the reactants and the product, propyl benzene. The rate of reaction may be expressed by the equation:

$$\frac{dv}{dt} = \frac{k[GaCl_3]\,[C_3H_7Cl]\,[C_6H_6]}{[C_6H_6] + K[C_3H_7Cl]}$$

where k = 750 and K = 0.5. With aluminum chloride the results agree partially with the above mechanism, but an additional factor is the formation of a complex of the product and catalyst.

A saturated Kogasin II having an average molecular formula of $C_{14}H_{30}$ may be chlorinated and then condensed with aromatics to furnish a species of lubricating oil.[53] Halogenation of the synthetic hydrocarbon mixture at room temperature (20°C.) yielded a composite of five products containing from 1 to 6 chlorine atoms per molecule. Reaction of the trichloro derivative with 1 to 3 volumes of xylene and 5 per cent by weight of aluminum chloride gave a 75 per cent yield of alkylated aromatic hydrocarbons. A material for increasing the viscosity of lubricating oils is secured by the condensation of benzene and ethylene dichloride. The reactants are heated to 40°C. with a Friedel-Crafts condensing agent and distilled to purify the substituted hydrocarbon. Condensation at 70-80°C. gives a viscous liquid suggested for increasing the transparency and adherent properties of paraffin wax.[54] Shinkle, Brooks and Cady[55] report that a plastic material obtained from this reaction at 110°C. finds application as a compounding agent for natural and synthetic rubber. According to Moran,[56] benzene and ethylene chloride begin to combine spontaneously when placed with aluminum chloride in a porcelain-lined kettle. The temperature should be held at 40-50°C. for 24 hours and then raised to 60-70°C. for 10 minutes and cooled again to 50°C. A few minutes after the temperature is lowered the mass will swell to about three times its original volume, forming a plastic material. Dichloroethane and benzene may also be united with oleic acid by the Friedel-Crafts synthesis.

Also, Ulich and Heyne[57] have investigated the speed of the condensation of benzoyl chloride and benzene in carbon disulphide solution, using gallium and aluminum chlorides as condensing agents. The extent of arylation was determined by measuring the volume of hydrogen chloride evolved. Condensation may be represented as:

With equimolecular proportions of benzoyl chloride and catalyst the reaction is unimolecular but does not go to completion because of the formation of a complex between benzophenone and the contact agent resulting in deactivation of the latter.

FIG. 189.—Plant for Manufacture of Paraflow.

Trichlorodiphenylmethane is suggested as a transformer oil, one of its reported properties being non-inflammability. It may be prepared by condensing trichlorobenzyl chloride with an excess of benzene using aluminum chloride as a promoter.[58] Barbier[59] reports that the Friedel-Crafts synthesis may be utilized to convert *p-ter*-butyltoluene to an isopropyl-4-*ter*-butyltoluene by adding isopropyl chloride to the former. Transformation of phthalic anhydride to phthalyl chloride by treatment with benzotrichloride and a condensing agent has been proposed.[60] Reaction in the liquid phase at a temperature of 60° C. with zinc chloride as catalyst is said to give 95 per cent of the theoretical yield.

Condensation of halogenated heavy hydrocarbon material such as chlorinated paraffin wax, petrolatum or paraffin oil with aromatic hydrocarbons, e.g., naphthalene, gives products adaptable as pour point suppressors for lubricating oils.[61] In one process, 100 g. of a chlorinated wax are admixed with 10 g. of naphthalene and placed in a reaction chamber. The latter is equipped with a steam coil, agitator and a swiveled pipe which is designed to facilitate removal of the reaction products. The mixture of halide and aromatic is heated to 130-140°F. and 10 g. of aluminum chloride slowly incorporated. The reaction chamber is maintained at the above temperature for a period of 1 hour after the aluminum halide has been added. At the end of this time, carbon tetrachloride is employed to extract the condensed products which comprise the upper layer. These may then be drawn off through the swiveled pipe. A synthetic lubricating oil said to be free of resinous material has been formed by condensation of chlorinated paraffin wax with biphenyl.[62] Thus, 5 g. of biphenyl and 15 g. of aluminum chloride were dissolved in 200 g. of naphtha and the solution heated to 130-140°F. (55-60°C.). The chlorinated wax was then incorporated gradually into the solution and the mixture allowed to stand for a period of 2 hours. At the end of that time, the aluminum chloride was separated from the oily layer and the latter distilled to remove naphtha. In this

manner, a yield of 84 per cent of a light-colored oil, which is not susceptible to large viscosity changes with variations in temperature, was said to be secured.

Alkyl groups may be substituted in phenols by employing any of the agents specified for the Friedel-Crafts reaction (aluminum, ferric or zinc chloride). For example, Seymour[63] treated phenol with *ter*-butyl chloride at 80-90°C. in the presence of hydrated ferric chloride to obtain mainly *ter*-butylphenol. To obviate separation of unchanged butyl chloride from the hydrogen chloride leaving the reaction zone the mixed vapors may be passed into tertiary butyl alcohol, thus converting the hydrogen chloride into additional butyl halide.[64] *ter*-Butylphenolic compounds have been recommended as germicides, fungicides and preservatives[65] and also for the preparation of oil-soluble resins by condensation with aldehydes.[66] A highly alkylated aromatic ether resembling a lubricating oil and reported to have many properties of the latter has been produced from a chlorinated paraffin (containing 17 per cent of chlorine) and diphenyl ether.[67] Condensation is effected at 60°C. with a small portion of a Friedel-Crafts agent. Reichstein, Rosenburg and Eberhardt[68] report that methyl pyromucate reacts with *ter*-amyl chloride, when aluminum chloride is present, to furnish 5-*ter*-amylfuran-2-carboxylic acid, according to the equation,

The latter compound, which boils at 108-110°C. under 11 mm. pressure, may be oxidized by potassium permanganate to dimethylethyl acetic acid.

REACTION OF HALIDES OF PARAFFINS AND CYCLOPARAFFINS WITH SULPHITES

The reaction of aliphatic halides with aqueous solutions of sulphites is known as the Strecker reaction. For example, ethyl iodide will combine with sodium sulphite to give sodium iodide and sodium ethyl sulphonate.[69]

$$C_2H_5I + Na_2SO_3 \longrightarrow NaI + C_2H_5SO_3Na$$

Hemilian[70] reported that when ammonium sulphite is employed for this double displacement, the end of the reaction is very definitely marked.

$$RCl + (NH_4)_2SO_3 \rightleftharpoons NH_4Cl + R{-}NH_4SO_3$$

From the latter compound the acid may be obtained by boiling with lead dioxide and subsequently acidifying the lead salt. The method was used to prepare α-sulphobutyric acid,  $CH_3CH_2CH(SO_3H)COOH$, from the corresponding bromo compound and β-sulphobutyric acid,

$$CH_3 \cdot CHSO_3HCH_2COOH$$

from the chloro compound. In the same manner Wagner and Reid[71] synthesized a number of aliphatic sulphonic acids containing from 1 to 6 carbon atoms. Sulphonic acids did not result in the case of *sec*-amyl, *n*-hexyl, *sec*-hexyl and phenyl halides, though with halides of lower carbon content some sulphonic acids were obtained.

The above general reaction has been employed in making sulphonic acids from low-molecular-weight polyhalogenated hydrocarbons. In one process methylene iodide and aqueous sodium sulphite are allowed to interact at a temperature of 70°C., furnishing a 95 per cent yield of sodium iodomethane sulphonate.[72] Aurisicchio[73] employed triiodomethane instead of the dihalide. The reaction is carried out under reflux for a period of 5 hours at 70°C. The sodium iodide formed is decomposed by a stream of chlorine. Carbon dioxide is passed in to displace residual chlorine, and after removal of water ethyl alcohol is added to throw out the sulphonate. Use of copper as a contact agent and maintenance of a temperature of 120-140°C. in this reaction have also been recommended.[74] According to Lauer and Langkammerer[75] 0.6 mole of potassium sulphite mixed with 0.2 mole of triiodomethane and refluxed for 4 hours at 70°C. furnishes 73 per cent of the theoretical yield of potassium iodomethane sulphonate. Further treatment of the latter compound with potassium sulphite gives potassium methionate, $CH_2(SO_3K)_2$. The formation of β,β-disulphopropionic acid from potassium α,β-dibromoproprionate and potassium sulphite has been described by Backer and Beute.[76] Potassium α-bromo-β-sulphopropionate is first produced and splits off hydrogen bromide to become potassium β-sulphoacrylate. Further reaction of the latter with potassium sulphite yields β,β-disulphopropionic acid (potassium salt).

$$CH_2Br{-}CHBr{-}COOK + K_2SO_3 \longrightarrow KO_3S{-}CH_2{-}CHBr{-}COOK \longrightarrow$$
$$KO_3S{-}CH{=}CH{-}COOK \longrightarrow (KO_3S)_2CH{-}CH_2{-}COOK$$

A number of alkane disulphonates in which the sulphonate groups are attached to the terminal carbon atoms have been prepared by Stone.[77] Alkane dibromides of the general formula $Br(CH_2)_nBr$ were reacted with sodium sulphite.

$$Br(CH_2)_nBr + 2Na_2SO_3 \longrightarrow NaO_3S(CH_2)_nSO_3Na + 2NaBr$$

One mole of the dibromide was added to an aqueous solution of 2.5 moles of sodium sulphite preheated to 100°C. The reaction time varied from 12 hours to 7 days. Aliphatic compounds containing more than 6 carbon atoms in a straight chain, with one halogen and one hydroxyl group on opposite terminal atoms, may be employed to produce a sulphonate by the Strecker reaction.[78] For example, 6-chloro-1-hexanol is converted to 6-hydroxyhexane-1-sulphonic acid by reaction with sodium sulphite at 170-180°C. The hydroxyl group may then be esterified with octoic or *n*-decylic acid. Reed and Tartar[79] report that the sulphonates of paraffins containing a large number of carbon atoms may be obtained by heating 1 mole of the corresponding alkyl bromide with 1.15 moles of aqueous sodium sulphite in an autoclave for a period of 9 hours at 180-200°C. After reaction the solution is evaporated to dryness and extracted with petroleum ether. In this manner the *n*-octyl, *n*-decyl, lauryl, myristyl, cetyl and *n*-octadecyl sulphonates were secured.

It is interesting to note that the Strecker reaction may be used with unsaturated halides in some cases. α-Sulphoacrylic acid is prepared from ammonium α-bromoacrylate, *cis* and *trans*-β-sulphoacrylic acid from β-chloroacrylic acid, and β-sulphocrotonic acid from ammonium β-chlorocrotonate, all by treatment with ammonium sulphite.[80]

Backer[81] states that diethyl ether-2,2′-dichloride reacts with ammonium sulphite to give diethyl ether-2,2′-disulphonic acid.

$$ClCH_2CH_2{-}O{-}CH_2CH_2Cl + (NH_4)_2SO_3 \longrightarrow H_4NO_3SCH_2CH_2{-}O{-}CH_2CH_2SO_3NH_4$$

The latter may be heated to 55°C. at 1 atmosphere pressure and treated with hydroxylamine (NH_2OH), yielding aminoalkylsulphonic acids.[82] Schindhelm and Bayer[83] point out that sodium sulphite replaces chlorine in 2-chlorobenzothiazole at 100°C. to furnish benzothiazole-2-sulphonic acid. 2-Chlorobenzoxazole is similarly converted to benzoxazole-2-sulphonic acid.

FIG. 192.—Plant Assembly for Production of Aralkyl Ketones by Friedel-Crafts Reaction. (P. H. Groggins)

DOUBLE DECOMPOSITION OF SALTS OF INORGANIC ACIDS WITH ALKYL AND ARYL HALIDES

Alkyl halides undergo double decomposition with metallic cyanides to form nitriles which may then be oxidized to the corresponding acids.[84] For example, 1 mole of amyl chloride refluxed for 48 hours with 1.1 moles of sodium cyanide in a solvent of 80 per cent ethanol and 20 per cent water gave an 80 per cent yield of nitrile. However, when an equimolecular proportion of sodium iodide was added to the reaction chamber, the yield increased to 90 per cent. This was attributed to the formation of amyl iodide, which is more reactive than the chloride.

$$\begin{aligned} C_5H_{11}Cl + NaI &\longrightarrow C_5H_{11}I + NaCl \\ C_5H_{11}I + NaCN &\longrightarrow C_5H_{11}CN + NaI \end{aligned}$$

Rosenmund and Struck[85] stated that halogen atoms attached to the nucleus of an aromatic hydrocarbon can be replaced by the cyanide group if a mixture of potassium and cuprous cyanides is employed and the temperature maintained at 200°C. The formation of the aromatic nitrile was found to take place regardless of whether or not other substituents or other halogens were present on the nucleus. On the other hand Feist[86] points out that the replacement of chlorine in phenyl chloride by this method is tedious and the yield of benzoic acid low, and in the case of 1,2,4-trichlorobenzene and hexachlorobenzene no nitrile or acid is formed. Mellitic acid, $C_6(COOH)_6$, was secured, however, from tetrachlorophthalic acid by the above procedure.

The alkyl halides will also react with alkali hydrosulphides to yield mercaptans. Thus, ethyl chloride may be treated with sodium hydrosulphide to secure ethyl mercaptan. By condensing the latter with acetone in the presence of zinc chloride and subsequently oxidizing the mercaptol, sulphonal, a hypnotic drug, is obtained. Treatment of polychlorinated paraffins of higher carbon content than octane with an alcoholic solution of a hydrosulphide and subsequent mild oxidation with nitric acid is reported to yield emulsifying agents applicable in textile and pharmaceutical industries.[87] Reaction of aliphatic mercaptans with aliphatic compounds containing replaceable halogen gives aliphatic sulphides, those of high molecular weight having a soapy character.[88] In this manner the sodium salts of α-(ethylmercapto)-stearic acid, dodecylmercaptoacetic acid and dodecyl-β,γ-dihydroxypropyl sulphide have been prepared.

According to Salzberg and Bousquet[89] dodecyl chloride dissolved in ethanol and treated with sodium thiocyanate for 8 hours at 125°C. forms dodecyl thiocyanate which may be employed as an insecticide.

REACTIONS OF HALOGEN DERIVATIVES OF PARAFFINS AND CYCLOPARAFFINS WITH MAGNESIUM

When alkyl halides are treated in ether solution with magnesium, direct combination takes place with a resulting formation of magnesium alkyl halides classed with the Grignard reagents.[90] The same reaction occurs with some of the aromatic halides, though in certain cases a solvent is not required. The Grignard reagent has been employed to great extent in experimental work, especially in organic syntheses and in the qualitative determination of alkyl halides.[91] Industrial use is limited, however, because of the relatively high cost of magnesium and the difficulty of recovering the latter in a metallic state. However, in the preparation of lead tetraethyl (tetraethyl plumbane), ethyl magnesium chloride and lead bromide have been employed. The lead ethide has been utilized as an antiknock agent for internal combustion engines.[92] Other compounds of this type, but containing the diethylmethyl radical, have also been suggested as knock-suppressors. Thus dimethyl bis(diethylmethyl)lead can be prepared by adding diethylchloromethane and methyl iodide to a mixture of lead chloride, magnesium and ether.[93] In the procedure, 48 g. of metallic magnesium were placed in a glass reaction flask together with 277 g. of lead chloride. Diethyl ether (148 g.) was employed as a solvent for reaction products. A mixture of 106 g. of diethylchloromethane and 141 g. of methyl iodide were then incorporated dropwise in the mixture. At the end of a contact period of 1 hour, the reaction products were cooled to 0°C. Dilute hydrochloric acid was then added slowly to bring about a separation of the ether layer. The latter contained the dissolved dimethyl bis(diethylmethyl)lead.

Materials advocated as disinfectants, insecticides or fungicides and also as antioxidants or paint driers may be prepared by heating a lead tetra-alkyl with a phenol in the presence of silica gel.[94] For example, 14.5 g. of phenol and 49 g. of lead tetraethyl were heated at 150-155°C. for 2.5 hours in the presence of 0.25 g. of silica gel. At the end of that time the reaction mixture was cooled to 20°C. and solidified. The solid material was recrystallized from benzene. In this manner 38 g. of triethyl lead phenolate, a yellow powder which decomposes at 205°C., were said to be obtained.

In an analysis of a mixture of alkyl chlorides, it has been found advantageous to convert the chloride to the corresponding anilide and determine the melting point of that substance.[95] The reason for this step is that the anilides of isomers of the alkyl chlorides have sharply defined melting points which differ from each other.[96] To secure the anilide, the chloride is first converted into the corresponding Grignard compound which is then treated with phenyl isocyanate, C_6H_5NCO. In some cases the toluides and α-naphthylamides are also useful for the same purpose. The melting points of some of the anilides are given in Table 169.

Although at 5 to 15°C. butyl and isoamyl chloride react with magnesium to form a Grignard compound, use of higher temperatures (78 and 99°C., respectively) results in violent reaction producing olefins, paraffins and magnesium chloride, according to the equation[97]

$$2C_nH_{(2n+1)}Cl + Mg \longrightarrow MgCl_2 + C_nH_{2n} + C_nH_{2n+2}$$

TABLE 169.—*Melting Points of Anilides Derived from Alkyl Chlorides.*

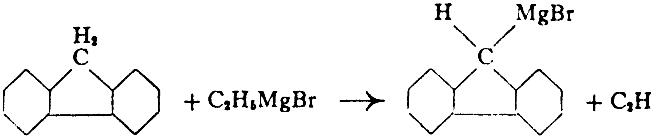
Chloride	B.P. of Chloride °C.	M.P. of Anilide °C.
Methyl	− 23.7	112-113
Ethyl	12.5	104-104.5
Isopropyl	36.5	104-104.5
n-Propyl	46.5	91-92
ter-Butyl	51	132-133
sec-Butyl	68	105.5-106.5
Isobutyl	68.5	109-110
n-Butyl	78	62-63
ter-Amyl	86	90-91
3-Chloropentane	96.7-97.1	126-127
2-Chloropentane	96-97	86-87
Isoamyl	99	110-110.5
n-Amyl	106	94-95

According to Flood and Calingaert[98] *ter*-butyl chloride and magnesium do not form an alkyl magnesium chloride. Instead, at 10-15°C., isobutene, isobutane and small proportions (10 per cent) of hexamethylethane, diisobutylene and higher polymers are secured.

Some alkyl bromides, also, do not lead to Grignard reagents when treated with magnesium. Ethylene bromide, for instance, is said to break down to ethylene and magnesium bromide dietherate [$MgBr_2$—$(C_2H_5)_2O$], if ether is employed as a solvent.[99] At most, a trace of ethylene magnesium bromide is found. 1,2,3-Tribromoisobutane when added to magnesium in ethereal solution also breaks down, furnishing diisobutenyl.[100]

$$2CH_3CBr(CH_2Br)_2 + Mg \longrightarrow [CH_2C({=}CH_2)CH_3]_2 + MgBr_2$$

As stated above, aromatic organo magnesium compounds may also be formed from the corresponding chlorides and in some cases a solvent is not required. Reaction of α-chloronaphthalene with magnesium (filings) at 200°C. is exothermic, with a reported yield of 16 per cent of naphthalene magnesium chloride.[101] Treatment of benzyl chloride in a similar manner furnished a resin whose structure was not determined. Miller and Bachman[102] report that magnesium suspended in ether readily combines with 9-bromo-phenanthrene to form an organo magnesium bromide in 92-93 per cent yield.[103] Fluorene also forms this compound by interaction with ethyl magnesium bromide in boiling xylene (144°C.) according to the equation,



The amount of 9-fluorylmagnesium bromide was estimated by measuring the volume of ethane evolved. Some of the results are indicated in Table 170.

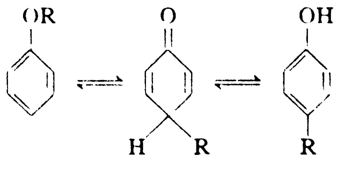
PRODUCTION OF ETHERS FROM CHLORINATED PARAFFINS

Alkyl and aralkyl halides condense with alkali alcoholates or phenolates to form ethers,

$$RX + NaOC_nH_{2n+1} \longrightarrow ROC_nH_{2n+1} + NaX$$
$$RX + NaOC_6H_5 \longrightarrow ROC_6H_5 + NaX$$

The second of these reactions seems to be effected more easily, and the aralkyl ethers obtained are said to be of industrial importance in dyeing.[104] Dispersing or emulsifying agents may be obtained by sulphonation of the ethers derived from chlorinated high-molecular-weight hydrocarbons. Similar treatment of phenoxy ethers derived from the same source furnishes leather solvents. A plastic material for molding compositions may be obtained from ethylene dichloride and sodium phenolate heated with ammonium carbonate at 160-190°C. for 6 hours.[105]

An alkyl ether of 1,2-dihydroxybenzene (pyrocatechol) may be prepared by treating the barium salt of the latter with methyl chloride.[106] Xylene is employed as an inert solvent and the temperature is maintained at 240°C. In a somewhat similar manner, a mixture of mono- and di-decyl ethers of a dihydroxy benzene may be secured.[106a]. Alkyl chlorides and alkali phenolates will also yield ethers.[107] For instance, ethyl alcohol is employed to dissolve 117 g. of sodium phenolate, to which is added 145 g. of diisobutyl chloride. The mixture is refluxed for 2 hours and the alcohol then evaporated. Water may be added to separate the salt and diisobutyl phenyl ether and the latter then washed with sodium hydroxide. The ether showed no evidence of rearrangement into a substituted phenol on being heated to 250°C. for 2 hours. In the case of *ter*-amyl and *ter*-butyl chloride, however, reaction of 1 mole of either of these substances with 1 mole of potassium phenolate at 75°C. leads to the corresponding phenyl ethers, but a rise in temperature to 125° C. for 2 hours, then to 180°C. for 1 hour, causes rearrangement to substituted phenols.



Employment of the latter as antiseptics and for the preparation of oil-soluble phenol-aldehyde resins has been suggested.[108] Some of the general rules for rearrangement given by Natelson follow:

[108] See Carleton Ellis, "The Chemistry of Synthetic Resins," Reinhold Publishing Corp., New York, 1935.

1. All alkyl or cyclohexyl phenyl ethers will form equilibrium mixtures of ether and substituted phenol at high temperatures (175-250°C.).
2. Increase in the molecular weight of the alkyl group favors production of substituted phenols.
3. If the ether-forming carbon of the alkyl group is tertiary, a greater percentage of substituted phenols will result than with a secondary or primary carbon atom.
4. A negative group attached to the ether-forming carbon shifts the equilibrium in favor of substituted phenol formation.
5. Substituting an alkyl group in the phenyl nucleus of an alkyl phenyl ether leads to increased amounts of ethers.
6. Equilibrium mixtures of ortho- and para-substituted phenols are obtained on rearrangement.

Vaughn, Vogt and Nieuwland[109] have studied the condensation of a number of alkyl halides with sodium alcoholates in a solution of liquid ammonia. The temperature was maintained between —33° and —10°C. and the pressure between 1 and 10 atmospheres. The chlorides were found to be almost unreactive. Bromides gave the highest yields of ethers, together with some olefins. Because of the formation of olefins, the iodides were not effective in bringing about large yields of ethers. Some of the results of this investigation are shown in Table 171.

TABLE 171.—*Yields of Ether from Alkyl Halides and Sodium Alcoholates.*

Sodium Derivative of	Alkyl Halide	Time Hours	Pressure Atm.	Product	Yield %
n-Propanol	Propyl bromide	1.5	1	Dipropyl ether	12
n-Butanol	Butyl bromide	1	1	Dibutyl ether	8
n-Butanol	Butyl bromide	1	10	Dibutyl ether	28
n-Pentanol	Amyl chloride	2	2.7	Diamyl ether	3
n-Pentanol	Amyl bromide	2-5	1.7-2.7	Diamyl ether	32-33
n-Pentanol	Amyl iodide	2	2.7	Diamyl ether	17
n-Pentanol	Butyl chloride	2	3	Amyl butyl ether	0
n-Pentanol	Butyl bromide	2	3	Amyl butyl ether	28

Ethyl sorbitol ether has been obtained by reaction of ethyl chloride with sorbitol in aqueous alkaline solution, treatment taking place in a nickel autoclave at 140-155°C. for 5 hours.[110]

It is interesting to note that aralkyl halides will also condense with alcohol to form ethers. According to Nixon and Brauch[111] the reaction of triphenylmethyl chloride in an excess of alcohol is a unimolecular mechanism, with the reaction-rate constant proportional to the initial concentration of the halide. The energy of activation of triphenylmethyl chloride is reported to be 13,420 cal. per mole.

The reaction of alkyl and aryl halides with sodium leads to the formation of free radicals, though in the case of the aryl radicals there seems to be some disagreement as to their nature. The reaction between sodium vapor and methyl or ethyl bromide is said to proceed according to the equation,[112]

$$\mathrm{Na} + \mathrm{RBr} \rightleftharpoons \mathrm{NaBr} + \mathrm{R}$$

The presence of free radicals at a distance of 8 cm. from the point of formation was detected by reacting the radicals with chlorine and iodine. Horn and

Polanyi[113] report that the action of sodium vapor on bromobenzene gives gaseous phenyl. On the other hand, Morton and Stevens[114] hold that there is an intermediate step in this reaction, the formation of a complex of bromobenzene and sodium, designated as a "metal halyl." The reaction was explained to be

Dotted lines represent partial valences, some of which serve to bind the phenyl radical and the sodium to the polar atom, and others which are unsaturated and represent unused combining power. As may be seen from the above course of reaction, the "metal halyl" eventually becomes a free phenyl radical. Also, it has been stated that sodium promotes reaction between aromatic hydrocarbons and alkyl halides which in its absence would be relatively inert to each other. For example, 100 g. of anthracene may be dissolved in 500 cc. of diethyl ether and 35 g. of powdered sodium added. Treatment with 165 g. of isoamyl chloride gives 9,10-diisoamyl-9,10-dihydroanthracene.[115] An analogous reaction takes place in the case of phenanthrene and isobutyl chloride, dihydrodiisobutylphenanthrene being obtained.[116]

In the manufacture of sulphide plastics, alkyl halides and caustic soda may be employed. In a process described by Ellis,[117] aqueous caustic soda is mixed with sulphur and refluxed to dissolve the latter. Methanol, ethylene chloride and formaldehyde are added to the sodium polysulphide and the composite is heated to 80°C. for several hours, then cooled gradually. A resinous plastic which is said to have strong coherence and which may be drawn into threads or sheets results The above type of reaction in the presence of copper sulphate is reported to furnish an unsaturated hydroxylated hydrocarbon suggested as a lubricant.[118] Thus, 115 g. of chlorinated paraffin containing 3 chlorine atoms per molecule and having a molecular weight of 367 were admixed with 225 g. of aqueous caustic soda and 5 g. of copper sulphate. The reaction was effected in an autoclave by heating to 220-225°C. for 16 hours. Hydrochloric acid was then added to the products until the latter showed an acid reaction, at which point an oil layer was said to be formed. The latter was reported to contain 88 g. of a light brown oil, having 1 chlorine atom per molecule. In one method, chloroethylether, instead of ethylene chloride, is a reactant.[119] Caustic soda, magnesium chloride and sodium polysulphide in aqueous solution are heated with 2,2′-dichloroethyl ether. The condensation product obtained may be employed in vulcanizing rubber.

Hydrolysis of methyl(chlorophenyl)chloromethane with aqueous caustic soda and subsequent treatment with concentrated sulphuric acid to dehydrate the methyl (chlorophenyl)carbinol is suggested for the production of chlorostyrene.[120] The equations for the procedure are

$$ClC_6H_4CHClCH_3 \xrightarrow{NaOH} ClC_6H_4CHOHCH_3 \xrightarrow{H_2SO_4} ClC_6H_4CH{=}CH_2$$

Methylenepyrocatechol may be secured in 20 per cent yield from this phenol, potassium hydroxide and methylene chloride.[121] The method consists of heating a suspension of 50 g. of pyrocatechol, 40 g. of potassium hydroxide and 140 g. of methylene chloride in 200 cc. of water. The reaction chamber is an autoclave in which a temperature of 120°C. is maintained during the time of contact, 24 hours. The following properties are reported for methylenepyrocatechol:

Boiling point (11 mm.) 57°C.
d^{20}_{20} 1.185 n^{20}_{D} 1.53867

Trichloromethyl-*p*-chlorophenylcarbinol and the corresponding tribromo compound have been obtained by addition of chloroform and bromoform to *p*-chlorobenzaldehyde.[122] The trichloromethyl compound boiled at 187-188°C. under 26 mm. pressure, and the tribromo derivative had a melting point of 90-91°C. Dehalogenation of alkyl halides furnishes a means of obtaining pure hydrocarbons. For example, to obtain heptane, 179 g. of heptyl bromide are heated with 400 g. of zinc and 500 cc. of ethyl alcohol at 78°C. for 12 hours.[123] At the end of that period the mixture is distilled and refluxed with potassium hydroxide, the oily layer separated and again distilled. The yield is said to be 79 per cent.

Alkyl halides undergo double decomposition when treated with thiosulphate salts, furnishing, in the case of the monohalides, substances which are said to be effective as emulsifying agents and as plastics in the case of dihalides. In one procedure, *n*-dodecyl iodide and ammonium thiosulphate are heated to 78°C. in an ethanol solvent to obtain *n*-dodecyl ammonium thiosulphate, which is used as a soap.[124] Twiss and Neale[125] have prepared sulphides reported to be applicable in increasing the oil-resistant properties of rubber. Ethylene chloride was caused to interact with sodium thiosulphate in aqueous ethanol at 75°C. The alkene thiosulphate was then acidified by acetic acid and heated with hydrogen peroxide.

Acetylene carboxylic acids may be prepared from 1,2-dibromobutane and sodium amide.[126] The latter is mixed with kerosene and the dihalide incorporated at a temperature of 145°C. At the end of the reaction period (2.5 hours) the volume of the mixture is doubled by addition of a diluent such as ethyl ether. A stream of carbon dioxide is then conducted into the solution to form the ammonium salt of the acid which on treatment with hydrochloric acid yields ethyl propiolic acid ($CH_3CH_2C{\equiv}CCOOH$). Lesbre[127] points out that sodium plumbite and ethyl iodide react according to the equation:

$$Pb(ONa)_2 + C_2H_5I \longrightarrow C_2H_5PbOONa + NaI \xrightarrow{HOH} C_2H_5PbOOH$$

The resulting ethyl plumbonic acid is said to be amphoteric, amorphous and infusible.

In the manufacture of lead alkyls as antiknock agents for motor fuels several methods employ the reaction of alkyl halides with lead-sodium alloys.[128] To reduce hazards in large-scale production of lead tetraethyl it has been suggested that the alloy be first heated to 35-55°C. and then activated with a small proportion of ethyl chloride before the remainder of the latter is added to the reaction.[129] Voorhees[130] proposed to make lead compounds for knock suppression directly from gasoline. In the procedure a mixture of fused sodium chloride and lead was electrolyzed in a cell having an anode of graphite and a cathode of molten lead (see Fig. 194). In this manner a lead-sodium alloy was formed at the cathode, while chlorine was liberated at the anode. The latter vapor was employed to halogenate a gasoline fraction containing a small proportion of ethane. The chlorinated gasoline and lead-sodium were then conducted into a reaction vessel. A portion of the halogenated hydrocarbon was first vaporized to aid in atomizing the alloy. When the two substances were admixed, lead tetra-alkyls were said to be formed in the gasoline. In this manner, the danger of industrial poisoning from lead tetraethyl was said to be reduced.

Chloroethanes, on treatment with sulphuric acid, lead to sulphates and carboxylic acids. To obtain glyoxal sulphate, tetrachloroethane is heated to 55-60°C. and reacted with fuming sulphuric acid containing 65 per cent of sulphur trioxide, using a catalyst of mercuric sulphate. On cooling the mixture the glyoxal sulphate crystallizes and may then be filtered, washed with sulphuric acid and ice water and dried.[131] The formation of the sulphate may be expressed by the equation,

Dichloroacetic acid may be secured from pentachloroethane and 97 per cent sulphuric acid at 130-170°C. The concentration of acid is maintained constant by adding water at intervals as needed.[132] According to Larson[133] acetic acid may be prepared by subjecting a mixture of 95 parts of carbon monoxide, 5 parts of ethyl chloride, and 25 parts of water to a temperature of 325°C. and a pressure of 700 atmospheres. A contact agent of active carbon or silica gel is advocated.

Chapter 35

Extraction of Nitrogen Compounds from Petroleum

The presence of nitrogen compounds in shale oil[1] and coal oil[2] is well-known and the analytical constants and structures of many bases have been determined. These substances are composed, for the most part, of pyridines and their simpler substituted derivatives, such as pyridine carboxylic acid. On the other hand, investigations of petroleum fractions reveal that they contain a number of nitrogenous bodies whose structures are more complex.[3] These latter compounds seem to be hydroaromatic in character and therefore closely related to the alkaloids. Since naphthene hydrocarbons, containing rings of 5 carbon atoms, as well as polycyclic substances composed of aromatic or hydroaromatic nuclei, are found in petroleum and the acids derived from them known as naphthenic acids, those naphthenic compounds possessing nitrogen may be designated as naphthenic bases.

In general the nitrogen content of petroleum oils is low, in most instances being about 0.1 per cent. American petroleums appear to represent the two extremes, the paraffin-base oils from Pennsylvania containing only a trace and California oils the highest proportion. Peckham[4] reports that the latter has between 1.02 and 1.11 per cent of nitrogen. Caucasian oils, particularly those from the Baku fields,[5] are said to possess nitrogenous bodies to the extent of 0.006 per cent.[6]

McKee and Parker[7] have developed a method for the estimation of nitrogen bases (and unsaturated compounds) in petroleum distillates. They recommend extraction with 25 per cent acetic acid, which (they state) is more efficient than sulphuric acid which dissolves both nitrogen bases and olefins. Furthermore, acetic acid gives a clearer solution, dissolves more of the nitrogenous bodies and causes less polymerization than hydrochloric acid. To compare the three reagents, 5 cc. of oil were pipetted into a test bottle which had a neck of 6 cc. volume, graduated into 30 divisions. The bottle was cooled in iced water and 10 cc. (or 200 per cent by volume) of acid added. After stoppering, the bottle was allowed to remain in the cooling bath (with occasional shaking) for 30 minutes, except when acetic acid was employed. In the latter case 10 cc. of glacial acetic acid were added to the oil, the mixture shaken, then diluted with water and immediately centrifuged. More acid was then incorporated, to bring the oil layer within the range of the graduations and the container centrifuged for 2 or 3 minutes at about 1000 r.p.m. The percentage of extract was then ascertained from the decrease in volume of oil. Some of the results obtained in this manner are given in Table 172.

However, Bailey[8] reported that a completely satisfactory estimation of the

naphthene bases in petroleum may be effected by employing a modified Kjeldahl method. Using this method the nitrogen content of California oil was found to be only 0.82 per cent as a maximum instead of the somewhat higher figures previously published.

EXTRACTION OF NITROGEN BASES

The extraction of these bases from petroleum fractions with sulphur dioxide, hydrochloric or sulphuric acid has received some attention. For example, Bailey[9] suggests treating the distillate at 20°F. with liquid sulphur dioxide to obtain a composite consisting of this substance, hydrocarbon oil and bases. An aqueous solution of the acid sulphites of the latter compounds is obtained on agitating the mixture with cold water. The free bases may then be secured by the addition of alkali, e.g., caustic soda, to the solution. This method is illustrated diagrammatically in Fig. 195. Another procedure involves passage of anhydrous sulphur dioxide into a body of oil.[10] Some of the resulting salts of naphthenic bases are precipitated and separated by filtration while others remain suspended in the oil. The latter may be extracted with water. Moser[11] advocates the use of sulphuric acid after preliminary treatment of the hydrocarbons with sulphur dioxide. Dilute acid (15 per cent) is employed in the first step to prevent formation of resins. After withdrawal of the aqueous acid from the oil, the latter is contacted with concentrated acid to effect removal of nitrogenous bodies.

Schestakow[12] reports that petroleum distillates may be subjected to the action of dilute sulphuric acid, the latter then neutralized and steam distilled. In this manner he secured (from a Caucasian petroleum distillate) 0.006 per cent of a brown liquid which had the characteristic odor of pyridine, was insoluble in water but readily soluble in alcohol. It distilled between 260° and 370°C. and on analysis was found to contain 6.60 per cent nitrogen, 85.72 per cent carbon and 8.09 per cent hydrogen. In some instances the oil may be filtered through fuller's earth before treating with acid. After neutralization of the latter the napthenic bases then liberated are extracted with ether. With a sample of Baku petroleum this method was said to lead to the segregation of mixed bases containing a high percentage of quinoline.[13] Hydrochloric acid is also suggested as a solvent in place of ether. The acid liquor is subsequently treated with salt and the bases salted out are dissolved in chloroform. Fractional distillation of the latter solution furnished pyridine and quinoline.[14]

STRUCTURE AND REACTIONS OF NAPHTHENE BASES

The structures of many of the nitrogen bodies contained in petroleum have not been ascertained possibly (as previously mentioned) because they break down during distillation and refining operations. However, the indications are these compounds are closely related to the alkaloids.

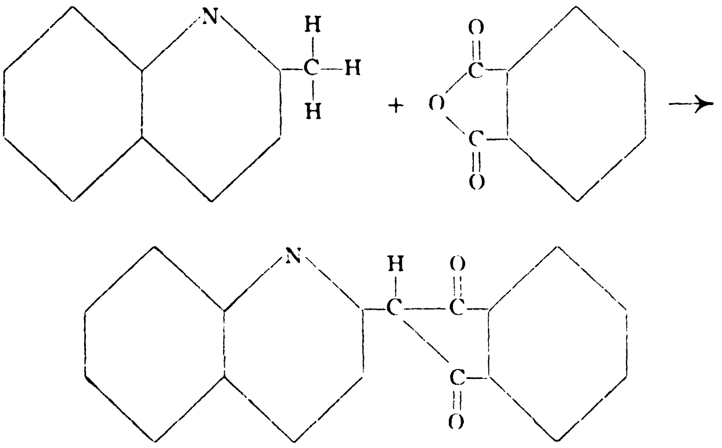
Distillation in vacuo of bases extracted from California petroleum resulted in the isolation of fractions whose molecular weights, analyses and boiling points are given in Table 173.[15]

TABLE 173.—*Naphthenic Bases from California Petroleum.*

Boiling Point °C.	Formula	Boiling Point °C.	Formula
139-140	$C_{12}H_{17}N$	223-225	$C_{15}H_{19}N$
197-199	$C_{13}H_{18}N$	243-245	$C_{16}H_{19}N$
215-217	$C_{14}H_{19}N$	270-275	$C_{17}H_{21}N$

These compounds reacted with platinum chloride to give crystalline precipitates and with chromic acid or neutral permanganate to form acetic acid, thus indicating the presence of short side chains and a tetrahydroquinoline ring.[16] Also these nitrogen-containing bodies united with bromine or iodine to yield addition products and with phthalic anhydride to furnish phthalones. The latter reaction suggested that the side chains were in the α- or γ-position in the nitrogen ring.



The first of the nitrogen compounds to be identified was 2,3,8-trimethylquinoline, which is present in a petroleum fraction boiling between 276° and 277°C. From this same portion an isomeric compound, $C_{12}H_{13}N$, and a base having the formula $C_{16}H_{25}N$ were also isolated. The separation of 2,3- and 2,4-dimethylquinoline from the cut boiling around 265°C. has been reported.[17]

The naphthene base $C_{16}H_{25}N$ represents a compound of the cyclopentane type, and may be the forerunner of structurally similar bases occurring in petroleum distillates. This substance is obtained from its picrate by heating the latter with ammonium hydroxide, washing with water and drying in a current of air. The material is a colorless, odorless, optically inactive oil, slightly soluble in water. It boils at 278.2°C. (746 mm pressure), has a specific gravity of 0.9391 at 20°C. (referred to water at 4°C.), and an index of refraction (with sodium light) of 1.5129 at 20°C. The structure originally assigned by Bailey and his co-workers was

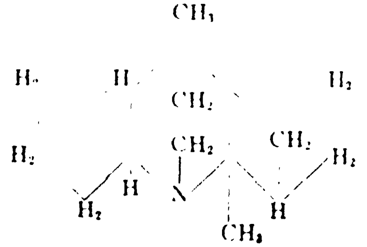
According to Lackey and Bailey,[18] this saturated naphthenic base, like quinoline methylated in position 2, condenses with phthalic anhydride to form a phthalone. It appears that although formaldehyde does not combine with this base as readily as with quinaldine (2-methylquinoline) nevertheless the reaction does take place at 200°C. The product can be oxidized with nitric acid to yield a dibasic acid, $C_{14}H_{19}N(COOH)_2$. The latter compound, on heating furnishes a monocarboxylic acid, $C_{14}H_{20}NCOOH$, from which an oxygen-free base was secured. This latter step is effected by converting the acid into its sodium salt and distilling it in the presence of soda-lime. The distillate is taken up in dilute hydrochloric acid, the solution washed twice with ether, and the base, $C_{14}H_{21}N$, liberated by the addition of caustic soda.

These investigators (Lackey and Bailey) stated that the base containing 14 carbon atoms exhibited resistance to hydrogenation. From this characteristic it was concluded that the parent compound (possessing 16 carbon atoms) is completely saturated. An unsaturated molecule would have resulted had either of the two carboxylic groups in the dibasic acid come from cleavage of a methylene or ethylene bridge followed by oxidation of these groups. Therefore, the existence of at least two methyls in the base $C_{16}H_{25}N$ is said to be confirmed.

The latter compound acts in an analogous manner to that of 2,4-dimethylquinoline in its behavior towards formaldehyde and on oxidation of the resulting product to a dicarboxylic acid. The analogy is further extended in the easy elimination of one carboxyl group on heating. All these reactions are reported to suggest the same relative positions of the two methyls to nitrogen as exists in 2,4-dimethylquinoline, so the following revised formula (with methyls in the α- and γ-positions to nitrogen) has been proposed.[18a]

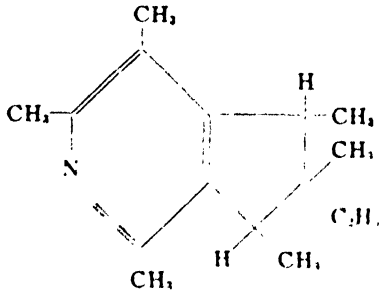


When bromine is added to this base a rather vigorous reaction takes place with evolution of considerable heat. A tough red gum is formed which slowly gives

---

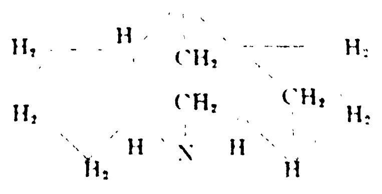
[18] R. W. Lackey and J. R. Bailey, *J.A.C.S.*, 1934, **56**, 2741; *Brit. Chem. Abs.* **A**, 1935, 357; *J. Inst. Pet. Tech.*, 1935, **21**, 50A; *Chem. Abs.*, 1935, **29**, 796.

[18a] J. R. Bailey (private communication) reports that some later work involving hydrogenation of the nitrogen base $C_{16}H_{25}N$ as well as its pyrolytic conversion to 2,3,6-trimethylpyridine appears to indicate it possesses a structure containing both a pyridine and an alkylated cyclopentane nucleus. One of several such possible structures may be represented by



off hydrogen bromide and is transformed into a heavy red liquid containing some free, admixed bromine. When agitated at 90°C. with 10 per cent caustic soda the liquid becomes colorless, and on drying and distilling under reduced pressure solidifies to a white crystalline solid with the following physical characteristics: m.p. 55.7°C., n_D^{60} 1.5268, n_D^{20} (subcooled liquid) 1.5431. This brominated base does not undergo the Fittig reaction,[19] is unaffected by heating with metallic sodium at 250°C., cannot be transformed into a Grignard reagent and is unchanged by prolonged refluxing with alcoholic or aqueous potassium hydroxide. Furthermore, it is not oxidized by either nitric acid or potassium permanganate in acetone solution. Efforts to replace the halogen by heating with silver acetate in glacial acetic acid were ineffective. The bromine derivative is unchanged on lengthy heating at 250°C. with sodium methylate as well as on treatment with moist silver oxide or alcoholic silver nitrate. Zinc and acetic acid, however, readily removed the halogen. Failure to brominate the base $C_{14}H_{21}N$, obtained by the elimination of two methyls from the compound $C_{16}H_{25}N$, indicates that bromination of the higher homologue replaces a hydrogen of a methyl group.

As previously mentioned, the lower homologue may be prepared by condensing the naphthene base $C_{16}H_{25}N$ with formaldehyde, oxidizing the product to a dibasic acid, heating to remove one carboxylic group and distilling the monobasic acid over soda-lime. For example, 1 volume of base and 35 volumes of formaldehyde (37 per cent) are heated at 190°C. for 8 hours in a sealed tube. At the end of this period a heavy oil separates. The latter may be dissolved in ether and extracted with dilute hydrochloric acid. Subsequent addition of caustic soda causes precipitation of a viscous, colorless syrup which apparently cannot be crystallized. Oxidation of the formaldehyde condensation product is accomplished by refluxing one volume of the substance with 40 volumes of 1:1 nitric acid for 4 hours. Evaporation of the resulting solution served to expel the nitric acid and the residue was a reddish solid, of indefinite crystalline form, insoluble in water, but soluble in alcohol, ether or acetone. The yield of acid was 47 per cent of the theoretical. Heat treatment of the latter substance at 235-240°C. under a pressure of 30 mm. brings about sublimation of a white crystalline product, a monocarboxylic acid ($C_{14}H_{20}NCOOH$) melting at 218-220°C. This is converted into its sodium salt, and distilled (under reduced pressure) at temperatures slightly higher than 360°C. from soda-lime. The distillate is washed with hydrochloric acid and ether and the base precipitated by addition of sodium hydroxide. The structure proposed for this compound is



EXTRACTION OF NAPHTHENIC BASES

A method for separating aromatic from non-aromatic bases has been developed by Perrins and Bailey.[20] This resolution depends upon the relative insolubility of aromatic base hydrochlorides in chloroform or ethylene dichloride. Both types of bases are dissolved in 1:1 hydrochloric acid and the solution extracted with the organic liquid. The latter, in turn, may be washed with water. The aqueous layer always contains a high concentration of aromatic base hydrochlorides. By employing this method 2,8-dimethyl- and 2,4,8-trimethylquinoline were isolated from a mixture of kerosene bases. The former compound was secured from a petroleum fraction boiling at 253° to 256°C. and the latter from the cut boiling at 273°C. Another method of separating the two types of bases is to dissolve the mixture in alcohol or acetone and add sulphuric acid, forming insoluble acid sulphates of the aromatic bases and soluble acid sulphates of the non-aromatic ones.[21]

[20] T. S. Perrins and J. R. Bailey, *J.A.C.S.*, 1933, 55, 4136; *Chem. Abs.*, 1933, 27, 5742; *Brit. Chem. Abs.* A, 1933, 1305. See also, Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., Inc., New York, 1934.

A process of microdistillation, termed amplified distillation, has been found of service in the separation of naphthene bases in distillates.[22] It was stated that some difficulty was experienced in working with small samples. This, however, was overcome by adding 15 to 20 volumes of an inert "carrier" solvent, whose function was to flush out the last traces of one cut before the next one began to distil. In the procedure, a fraction of bases is added to a petroleum oil boiling over a somewhat wider temperature range. After fractionation, the nitrogen-containing compounds are removed from admixed hydrocarbons by extraction with sulphuric acid, and precipitated in the form of picrates. In this manner the components of a complex mixture, even when the total volume is only a fraction of a cubic centimeter, are said to be segregated in the order of their boiling points. (See Table 174.) It was reported, in one instance, that from 130 cc. of a California pressure distillate there were secured seven pyridine homologues, quinoline and quinaldine.[23] In each instance the hydrochlorides of the naphthene bases were extracted with chloroform to withdraw non-aromatic derivatives. A very small quantity of nitrogen-containing compounds was recovered from the combined extracts, and this proved to be aromatic in character. It was concluded, therefore, that the occurrence of non-aromatic bases in cracked gasoline was not to be expected.

TABLE 174.—*Bases from California Pressure Distillate.*

Product	Boiling Point	n_D^{25}	Isolated as
2-Methylpyridine	129.3°C.	1.4983	Picrate
2,6-Dimethylpyridine	144°C.	1.4953	Picrate
4-Methylpyridine	145.3°C.	1.5029	Picrate
2,5-Dimethylpyridine	157°C.	1.4982	$HgCl_2$ salt
2,4-Dimethypyridine	158°C.	1.4984	Picrate
2,4,6-Trimethylpyridine	170.3°C.	1.4959	$HgCl_2$ salt
3,5-Dimethylpyridine	171.6°C.	1.5032	$HgCl_2$ salt
Quinoline	238.1°C.	1.6245	Picrate
Quinaldine (2-Methylquinoline)	247.6°C.	1.6093	Picrate

Sulphur dioxide is reported to be efficient for the partial separation of these nitrogeneous materials. Although it forms addition compounds with both aromatic and non-aromatic types nevertheless some of these are fairly stable while others dissociate rapidly at room temperature. For example, to resolve 2,4- and 2,3-dimethylquinoline, a kerosene fraction boiling between 263° and 267°C. is extracted with the liquid dioxide. The extracted portion is then treated with an alcoholic solution of picric acid. The resulting precipitate is leached with hot glacial acetic acid which dissolves all picrates except that of 2,4-dimethylquinoline.

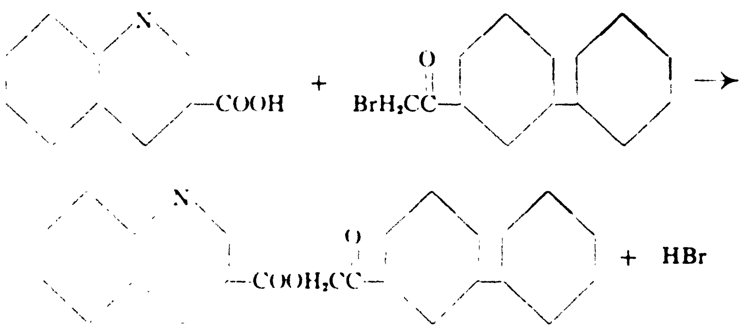
[23] A. C. Bratton and J. R. Bailey, *J.A.C.S.*, 1937, **59**, 175; *Chem. Abs.*, 1937, **31**, 1990.

These are orange colored needles. On cooling the acid the picrate of 2,3-dimethylquinoline crystallizes as microscopic hexagonal prisms melting at 231°C. Decomposition of the latter with alkali liberates the base as a white crystalline solid melting at 67°C. and boiling at 273°C.

Ganguli and Guha[24] point out that the nitrogeneous bodies extracted from an anthracene oil (boiling between 270° and 350°C.) cannot be separated by fractional distillation. That portion of the bases boiling from 180° to 200°C., under a pressure of 30 mm., was oxidized to carboxylic acids and their phenylphenacetyl esters prepared. To accomplish this the acids were dissolved in water, neutralized with caustic soda and a few drops of dilute hydrochloric (just sufficient to maintain a slight acidity) were added. Afterwards a solution of phenylphenacetyl bromide in ethanol was incorporated and the composite heated under reflux. On cooling, the esters precipitated.[25] Three phenylphenacetyl esters melting at 208°C., 201°C. and 101°C., respectively, were obtained. The first of these is reported to be that of quinoline (or isoquinoline) carboxylic acid and its formation may be represented as:



The fraction of bases boiling between 100° and 105°C. (under a pressure of 2 mm.) on reaction with an alcoholic solution of picric acid gave six picrates melting at 201°C., 181°C., 212°C., 230°C., 203°C., and 198°C., respectively. The structures of the first five were not determined, but the picrate melting at 198°C. was found to be a derivative of 5,8-dimethylquinoline. Of the others, the first four possessed the formula $C_{10}H_9N$ and seemed to be methyl quinolines or isoquinolines. The fifth one had the formula $C_{11}H_{11}N$ and was believed to be a dimethyl quinoline or isoquinoline.

Armendt and Bailey[26] investigated the fraction of kerosene bases distilling within the range of 215°-216°C. Fractional crystallization of the picrates, followed by distilling from soda-lime, yielded a colorless oil melting at 24.5°C. and boiling at 225.6°C. under a pressure of 750 mm. The formula of the base was reported to be $C_{13}H_{21}N$. On comparing with the naphthene base $C_{16}H_{25}N$ it was found that both resisted hydrogenation or dehydrogenation and were unaffected by alkaline permanganate. The basic compound ($C_{16}H_{25}N$) reacted with methyl iodide, but under similar conditions the methiodide of $C_{13}H_{21}N$ was not formed. The formula selected provisionally for the base containing 13 carbon atoms is

An interesting sidelight on the problem of the origin of nitrogen bases in petroleum has been noted.[27] To determine if non-aromatic bases (similar to those in petroleum) could be obtained from a stock containing proteins, carbohydrates and fats, an investigation was made of the compounds obtained on the distillation of cottonseed meal in a nitrogen-free lubricating oil.

The complexity of the cottonseed meal bases is reported to be comparable to those from petroleum. One of the marked dissimilarities is that one half of the first-mentioned substances are insoluble in petroleum ether. Another is that the higher boiling portions have a much greater nitrogen content than can be accounted for on the assumption of one nitrogen atom per molecule. Furthermore no evidence for the presence of a naphthene structure was obtained. The lower-boiling fractions (of cottonseed meal bases), however, did yield pyridine and a number of its homologues, identical with the products from coal, shale or bones. Coal-tar bases, such as quinoline, isoquinoline and lepidine, as well as the kero base[28] 2,3,8-trimethylquinoline were also found. Vacuum distillation of the high boiling protein-derived bases in an atmosphere of nitrogen led to the formation of colorless distillates which, unlike corresponding petroleum bases, soon darkened and precipitated tar. In the boiling range of 135° to 172°C. a total of 14 fractions of petroleum ether-soluble bases were secured. These consisted chiefly of pyridines, together with some pyrazines and diazines. The fraction in the range 172° to 215°C. had an abnormally high content of nitrogen and the presence of pyridine and quinoline was therefore considered excluded.

It is pointed out that these results should not be accepted as proof that petroleum bases are not of animal or vegetable origin. Bailey and his collaborators believe the assumption that the complex nitrogen compounds in crude oil arise from protein material does not necessitate the conclusion that a high temperature was involved in their formation. It would seem more probable that they resulted from bacteriological decay at ordinary temperature. The nitrogen in California petroleum does not exist in preformed basic compounds beyond a negligible amount and therefore the bases encountered in distillates are products of pyrolysis.

Nitrogen compounds of the pyridine series have been isolated from a fraction of Japanese shale tar.[29] According to Oparina and Smirnov[30] the shale-tar cut boiling between 140° and 145°C. may be condensed with benzaldehyde in the presence of zinc chloride. The three substances are reacted for 18 hours, and at the end of that period the portion distilling up to 200°C. is separated. On cooling this distillate distyrylpyridine is said to precipitate.

Another procedure for the recovery of methyl pyridines is based on carefully controlled precipitation with picric acid.[31] Application of this method to the low-boiling fractions of nitrogen bases from Japanese shale tar led to the isolation of a series of pyridine derivatives rich in α- and γ-alkyl substituted compounds. The majority of these contained methyl groups, though from the fraction boiling at 200° to 202°C. a base called pyrindane was obtained.

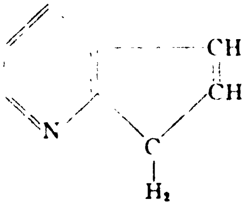
However, the name pyrindine has been suggested for the compound



and on this basis pyrindane becomes 5,6-dihydropyrindine.

USES OF NAPHTHENIC BASES

One of the uses of petroleum bases is as a pickling inhibitor. Rings and Kettle[32] prepared a pickling acid from sludge resulting from the treatment of

kerosene with sulphuric acid. The sludge is first neutralized with ammonia and ammonium hydroxide, then added to the oily layer produced by the preceding step. (See Fig. 197.) In this manner a basic extract is secured and removed from the mixture. The basic and acid extracts may then be agitated together, causing the formation of a layer which contains a mixture of acid oil and nitrogen bases. The composite is hydrolyzed and admixed with ammonium sulphate to segregate the inhibitor.

Among the other applications proposed for naphthenic bases are as insecticides[33] and as inhibitors in the autoxidation of lubricating oils.[34] Investigation of nitrogen bases from a sulphur dioxide extract of transformer oil has indicated that they have germicidal properties comparable with that of phenol.[35] Soap-solution emulsions of these water-insoluble bases did not exhibit germicidal action on strains of *Eberthella typhi* and *Staphylococcus aureus*, but solutions in 0.1*N* hydrochloric acid did. Growth of these bacteria was completely inhibited with some of these bases in dilutions as high as 1:600. Control tests without the bases showed that the acid content of these solutions was not the active germicidal agent.

Chapter 36

Oxidation of Petroleum Hydrocarbons. General Considerations

The great quantities of hydrocarbons available in crude petroleum or its fractions offer a source of materials for organic syntheses at relatively low cost. In consequence, the possibilities inherent in oxidation, which could convert these hydrocarbons into oxygen-containing substances of commercial value, make the study of such operations of industrial importance.[1] Such reactions offer a further advantage in that air is one of the raw materials. A great number of oxidation products have been reported as resulting from the various suggested processes, and in fact almost all possible permutations of oxy derivatives have been detected. For instance, alcohols, aldehyde-alcohols, aldehydes, ketones, aldehyde-acids, aldehyde-hydroxy acids, keto-acids, hydroxy-keto-acids and esters of these acids, both of the normal and of the lactonic ester type, have been found in the oxidized materials derived from a light petroleum distillate.[2] Oxidation carried to a very limited extent is effective as a dehydrogenation operation in converting paraffins to olefins, and naphthenes to aromatics. Certain processes have been suggested in which oxygen, after effecting such dehydrogenation, then serves as a catalytic agent for polymerization of the olefinic material to gasoline-like liquids.[3] The degree of accuracy required in the control of these oxidations varies both with the type of the initial hydrocarbon, and with the product desired. Ivanov and Savinova[4] reported a study of the oxidation of toluene, methylcyclohexane and *n*-heptane, using varying concentrations of hydrocarbon in air, and carrying out the reactions at different temperatures. In this instance hydrocarbons of differing degrees of complexity, acids, aldehydes, ketones and alcohols were obtained. It was found, however, that of these three seven-carbon hydrocarbons, *n*-heptane showed the greatest readiness to yield oxidation products before ignition occurred, the saturated cyclo-paraffin next, and the aromatic the least tendency to partial oxidation. Some hydrogen peroxide was found in the initial oxidation stage of the two non-aromatic hydrocarbons.

A great deal of work has been done in attempting to convert the higher hydrocarbons (e.g., paraffin wax) to acidic bodies which exhibit some properties analogous to those shown by the acids derived from natural fats and oils. Shoruigin and Kreshkov[5] investigated particularly the acids formed during oxidation (at 120°C.) of a wax melting at 52°C. The products consisted principally of hydroxy acids, lactones, lactides, fatty acids and their anhydrides, as well as unchanged and modified hydrocarbons, and lower partial oxidation products. The majority of these acids could not be distilled, even in a high vacuum. However, esterification with methyl alcohol yielded more volatile compounds. Distillation of the latter in vacuo permitted the separation of fractions which were mixtures of esters of hydroxy acids, and the average composition of which were represented by the empirical formulas

$$C_{13}H_{26}(OH)COOCH_3 \text{ to } C_{17}H_{34}(OH)COOCH_3$$

The more important industrial operations are, however, largely catalytic. Fokin[6] pointed out some years ago that the catalytic activity of a metal in oxidations or hydrogenations was proportional to its power to form different oxides or hydrides, respectively, and to the ease of the dissociation of these. Vanadium pentoxide, perhaps one of the most important oxidation contact agents in commercial practice, came into prominence during the 1920's, and has been used by many investigators with considerable success. If air and alcohol vapors are passed over the gently heated pentoxide (supported on asbestos) oxidation is vigorous enough to maintain the reaction temperature without external application of heat. In this instance the main products are acetaldehyde and acetic acid. According to Naumann, Moesse and Lindenbaum,[7] the catalytic activity of vanadium pentoxide is accounted for by the readiness with which the metal changes its valence from four to five and back, cyclicly, releasing active oxygen in each cycle, as follows:

$$V_2O_5 \rightleftharpoons V_2O_4 + O^*$$

Oxides of many of the heavy metals react similarly (e.g., the "blue oxides" of molybdenum), and have been proposed as applicable in a number of processes. On the other hand, metallic silver or copper, as well as their oxides, are useful particularly in the conversion of alcohols to aldehydes.[8] Oxidation of the type represented by the reaction of ethylene, carbon monoxide and steam to yield acids is catalyzed by a wide variety of substances, such as chlorides, metallic oxides, phosphoric acid and its acid salts.[9]

MECHANISM OF HYDROCARBON OXIDATION

The importance of hydrocarbon oxidation has inevitably lead to a great amount of study in an effort to understand and expound the mechanism of the reactions involved. Not only must slow oxidation of the hydrocarbons be comprehended for better control and production of intermediates, such as alcohols and aldehydes, but any wholly correct mechanism should include an understanding of the reactions taking place during explosive combustion. The latter is of special interest in consequence of its assistance to a more intelligent control of knocking in internal combustion engines. However, the very transient nature of the successive compounds formed during combustion renders a study of the problem exceedingly difficult. Much work has been done by spectroscopic means, making possible detection of radicals and compounds (particularly formaldehyde[10]) present in flames. However, the greatest amount of investigation directed toward complete elucidation of the mechanism has been done, probably, in connection with slow oxidation, since the records then are chemical analyses rather than spectrographic lines.

Three types of mechanism have been suggested. Bone proposed the hydroxylation mechanism by which oxidation of ethane, for instance, proceeds through the successive addition of atoms of oxygen at the carbon-hydrogen bond to produce first ethyl alcohol and then a dihydroxy ethanol which rearranges, with loss of water, to acetaldehyde.[10a] Steacie and Plewes advocate peroxidation whereby ethane (for example) is first dehydrogenated to ethylene, followed by addition of a molecule of oxygen to the unsaturated compound to give ethylene peroxide. This in turn reacts with ethylene to form ethylene oxide ( $\underset{O}{H_2C\text{———}CH_2}$), or with other intermediate oxy-compounds to furnish higher oxidation products. On the other hand, Norrish has developed a modification of the hydroxylation theory suggesting that there is a formation of free radicals which are the active chain-propagators.[11]

[8] See Chapter 38.

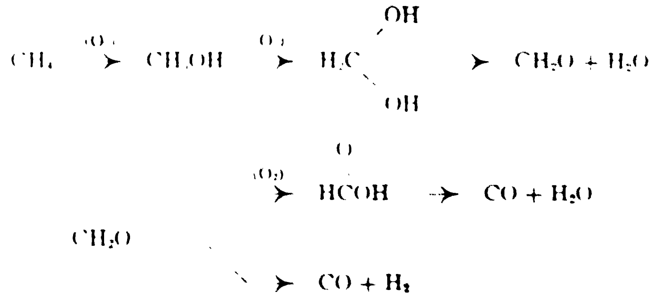
[9] See Chapter 39.

[10] L. Withrow and G. M. Rassweiler, *Ind. Eng. Chem.*, 1934, **26**, 1256; *Chem. Abs.*, 1935, **29**, 1235; *Brit. Chem. Abs.* **B**, 1935, 581. See also Chapter 44.

Most investigators agree on three necessary conditions which must be met: (a) that hydrocarbon oxidation proceeds only after the termination of an induction period which may endure for a fraction of a second or for several minutes; and (b) the mechanism must account for compounds known to be formed; and (c) there is a pronounced surface retardation phenomenon indicating that the reaction may be considered as a chain mechanism.[12]

Based on these concepts, three possible mechanisms have been developed. According to Norrish,[13] Bone has deduced his hydroxylation theory from the results of long continued experimentation and analytical work on the products formed. As a consequence, his explanation has been adapted to a static interpretation rather than to an understanding of the kinetics of the problem. Steacie and Plewes have paid particular attention to the kinetics of the problem, and the elucidation of the chain of reactions involved. Norrish's suggestion, involving a modification of the hydroxylation mechanism to include a reaction chain carried on by free radicals, has been put forward as adapting the rather static hypothesis. Bone favors the kinetics of chain reactions.

According to Bone and Gardner,[14] oxidation of methane proceeds as follows:



$$CH_4 \xrightarrow{(O)} CH_3OH \xrightarrow{(O)} H_2C\begin{smallmatrix}OH\\OH\end{smallmatrix} \rightarrow CH_2O + H_2O$$

$$CH_2O \xrightarrow{(O_2)} \overset{O}{HC}OH \rightarrow CO + H_2O$$

$$CH_2O \rightarrow CO + H_2$$

Norrish,[15] however, believes that this is not an adequate explanation, in that it does not account for the observed induction period, does not make provision for the action of catalysts and antiknock compounds and is inadequate to explain the effect of surface in reducing the observed induction period and also slowing the subsequent reaction. Finally, it leaves unexplained the observation that the ignition temperature of a given hydrocarbon-oxygen medium, under a given pressure, will vary when reaction tubes of different diameters are employed.

[10a] For the formation of methyl alcohol and ethyl alcohol during the oxidation of methane and ethane, respectively, see D. M. Newitt and J. B. Gardner, *Proc. Roy. Soc.*, 1936, **A154**, 329; *Brit. Chem. Abs.* **A**, 1936, 801; *Chem. Abs.*, 1936, **30**, 4460.

[11] See also Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., New York, **1934**.

[12] However, Semenov (N. N. Semenov, *Acta Physicochim.* (*U.R.S.S.*), 1934, **1**, 113; *Chem. Abs.*, 1935, **29**, 6823) reports that the oxidation of ethane is not influenced by surface-volume ratio. He suggests further that the reaction is "doubly heterogeneous," in that chain branching and breaking both take place on the walls equally, thus, effectively cancelling the influence exerted by surface.

[13] R. G. W. Norrish, *Proc. Roy. Soc.*, 1935, **A150**, 36; *Chem. Abs.*, 1935, **29**, 4920; *Brit. Chem. Abs.* **A**, 1935, 1081.

[14] W. A. Bone and J. B. Gardner, *Proc. Roy. Soc.*, 1936, **A154**, 297; *Brit. Chem. Abs.* **A**, 1936, 801; *Chem. Abs.*, 1936, **30**, 4461. See also, Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., New York, **1934**.

[15] R. G. W. Norrish, *loc. cit.*

Steacie and Plewes[16] report the hydroxylation mechanism is useful to predict products formed, but they do not consider it is satisfactory as a kinetic mechanism. Their observations show, furthermore, that the addition of excess oxygen may retard the rate of reaction after the induction period has passed, although the rate normally depends on some fairly high power of the concentration of the organic substance. This, they believe, taken in connection with the known retarding action of high surface-volume ratio, indicates that the reaction depends on a chain propagated by active molecules. Any excess oxygen tends to act as an "inert" diluent, and collisions between active hydrocarbon molecules and oxygen atoms tend to break the chain. The principal ending of the chain takes place at the surfaces of the vessel wall. However, since it has been observed that increased wall area decreases the induction period, though retarding the reaction once started, it is possible that the induction may involve a reaction between oxygen and, for instance, ethane absorbed on the surface of the reactor.

As previously mentioned, Steacie and Plewes are of the opinion that the first step in the oxidation of ethane is dehydrogenation to ethylene. In substantiation of this, they point to experiments in which ethylene-oxygen mixtures were heated until the induction period was passed and then ethane was added. This did not result in a new induction period, indicating that chains begun by ethylene may be continued by ethane. The complete oxidation of ethane, they believe, proceeds as follows:

$$\left.\begin{array}{lll} C_2H_6 + \frac{1}{2}O_2 & \longrightarrow & C_2H_4 + H_2O\ \text{(wall)} \\ C_2H_6 & \longrightarrow & C_2H_4 + H_2\ \text{(in the gas)} \end{array}\right\}\text{Induction period.}$$

$$\begin{array}{lll} C_2H_4 & \longrightarrow & C_2H_4^* \\ C_2H_4^* + O_2 & \longrightarrow & C_2H_4O_2 \\ C_2H_4O_2 + C_2H_4 & \longrightarrow & C_2H_4^* + \text{products} \\ C_2H_4O_2 + O_2 & \longrightarrow & \text{products} \\ C_2H_4O_2 + C_2H_6 & \longrightarrow & C_2H_4^* + C_2H_4 + H_2O_2 \\ C_2H_4^* + \text{surface} & \longrightarrow & C_2H_4\ \text{(Chain ends.)} \end{array}$$

(* Activated molecules).

One of the principal objections to this proposal mechanism is the fact that the hypothetical peroxide has not been detected by observers.[17] Steacie and Plewes[18] point out, however, that a substance suggested as the active agent in chain propagation should be unstable to secure continuity of the chain. However, according to Norrish[19] a further objection to this mechanism is that inert diluent gases do not exhibit the expected retarding action resulting from deactivation of active molecules:

$$C_2H_4^* + A \longrightarrow C_2H_4 + A$$

---

[16] E. W. R. Steacie and A. C. Plewes, *Proc. Roy. Soc.*, 1934, **A146**, 583; *Chem. Abs.*, 1935, **29**, 985; *Brit. Chem. Abs.* **A**, 1934, 1331.

[17] Higher paraffins, however, do form detectable peroxides which are comparatively stable, when oxidized at the lower temperatures. Thus A. K. Plisov (*Bull. soc. chim.*, 1936, (5) **3**, 1274; *Chem. Abs.*, 1936, **30**, 7829) reports oxidizing a Grozny paraffin wax melting at 52°C. by passing oxygen at the rate of 200 liters per hour through the liquid wax at 140° to 160°C. Active peroxides were found in the products which liberated iodine from potassium iodide, and oxidized ferrous salts. These peroxides were said to be stable to heat. A second class of peroxides was reported which were described as inactive, and did not react to the ordinary tests for peroxides. Both classes of peroxides are decomposed, the investigator states, by reaction in the presence of acids or alkalies.

[18] E. W. R. Steacie and A. C. Plewes, *Can. Chem. Met.*, 1934, **18**, 217; *Chem. Abs.*, 1935, **29**, 26.

[19] R. G. W. Norrish, *loc. cit.*

where A represents an inert molecule incapable of taking part in the reaction, but serving to deactivate the activated molecules of the reactants by collision with them. This investigator has proposed a modification of the hydroxylation theory, which provides for the kinetics of chain reactions by the assumption that free radicals are produced. The existence and possibility of free radicals have been shown by many other workers, particularly in the field of high-temperature pyrolysis of hydrocarbons.[20] Norrish suggests, therefore, that the main series of reactions involved in the oxidation of methane is:

$$\begin{aligned} O + CH_4 &\longrightarrow CH_2^{*} + H_2O + 48\text{ Cal.} \\ CH_2^{*} + \tfrac{1}{2}O_2 &\longrightarrow H_2CO + 15\text{ Cal.} \end{aligned}$$

These are repeated indefinitely, since they are mutually self-sustaining. They are ended, however, in either of two ways, the first of which is a ternary collision:

$$O + CH_4 + X \longrightarrow CH_3OH + X^{*} + 88\text{ Cal.}$$

where X represents an inactive molecule which is activated by the collision. This reaction is the source of any methyl alcohol produced. Formaldehyde is, then, the primary product, and the alcohol will appear only as the result of such ternary collisions. Hence, it would appear in quantity only under high pressure, or when a high concentration of an inert diluent gas is present. The second type of reaction tending to terminate the chain is:

$$O^{*} + \text{surface} \longrightarrow \tfrac{1}{2}O_2$$

Norrish proposes that the induction period represents the slow reaction of methane and oxygen molecules to yield formaldehyde and water, on the surface of the vessel, with the result that increased surface speeds the induction. The formaldehyde so produced can be oxidized, at low temperatures, to the fairly stable performic acid, but at the temperatures prevailing in slow oxidation of the hydrocarbon, he believes that formic acid and an atom of oxygen result. Much of the atomic oxygen will remain adsorbed on the surface of the vessel, but a considerable proportion will pass into the gases, acting as starting points for the chains. Thus, the complete reaction chain for ethane becomes:

$$\begin{array}{lcl} \left.\begin{array}{lcl} C_2H_6 + O_2 & \longrightarrow & CH_3CHO + H_2O \\ CH_3CHO + O_2 & \longrightarrow & CH_3COOH + O^{*} \end{array}\right\} \text{Induction} \\ \begin{array}{lcl} O^{*} + C_2H_6 & \longrightarrow & CH_3CH^{*} + H_2O \\ CH_3CH^{*} + O_2 & \longrightarrow & CH_3CHO + O^{*} \end{array} \end{array}$$

This is ended by:

$$\begin{aligned} C_2H_6 + O^{*} + X &\longrightarrow C_2H_5OH + X \\ O^{*} + \text{surface} &\longrightarrow \tfrac{1}{2}O_2 \end{aligned}$$

Secondary reactions take place, breaking the ethane and its oxy derivatives to methane and methyl compounds:

$$\begin{aligned} CH_3CHO + O^{*} &\longrightarrow CH_3COOH \longrightarrow CH_4 + CO_2 \\ CH_4 + O_2 &\longrightarrow H_2CO + H_2O \end{aligned}$$

However, Norrish proposes a different series of reactions in the combustion of ethylene, as follows:

$$\begin{aligned} C_2H_4 + O_2 &\longrightarrow 2CH_2O + 60\text{ Cal.} \\ CH_2O + O_2 &\longrightarrow HCOOH + O^{*} \end{aligned}$$

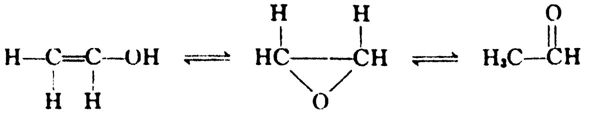
which is ended by:

$$O^{*} + C_2H_4 + X \longrightarrow C_2H_4O + X.$$

---

[20] **For a discussion of free radicals, see Chapter 2.**

Presumably, the compound C_2H_4O is vinyl alcohol, which is rapidly transformed into its isomers ethylene oxide and acetaldehyde:



vinyl alcohol ethylene oxide acetaldehyde

It will be noticed that following this mechanism, acetaldehyde will not be found as the primary product of ethane oxidation, but as an end product of the ternary collision in the ethylene oxidation. Norrish, however, reports that the aldehyde has been found in quantity among the products of ethane oxidation, but not in those from ethylene. Moreover, following this mechanism, methyl alcohol is unimportant in the oxidation of methane, and occurs only as an incidental product. According to Bone and Gardner,[21] methyl alcohol is a primary product, and they propose to modify the mechanism suggested by Norrish to the extent that methyl alcohol becomes the source of the active methylene radicals, thus:

$$\begin{array}{lcl} CH_3OH & \rightarrow & H_2C= + H_2O \\ H_2C= + O_2 & \rightarrow & H_2C=O + O^* \\ CH_4 + O^* & \rightarrow & CH_3OH \end{array}$$

Bone and Gardner point out that all stable intermediates postulated in this mechanism are found in quantity by analytical procedures.

Pease[22] studied the slow oxidation of propane, and from the results obtained, believes that the radical chain theory best accounts for the reaction. For this paraffin he proposes the following radicals:

$$\begin{array}{lcl} 2\,C_3H_8 & \rightleftharpoons & C_3H_8^* + C_3H_8 \\ O_2 + C_3H_8^* & \rightarrow & C_2H_6O + CH_3O^* \\ CH_3O^* + C_3H_8 & \rightarrow & CH_3OH + C_3H_7^* \\ C_3H_7^* + O_2 & \rightarrow & C_2H_4O + CH_3O^* \\ C_2H_4O + O_2 & \rightarrow & HCHO + CO + H_2O \\ 2\,CH_3O^* + M & \rightarrow & X \\ 2\,C_3H_7^* + M & \rightarrow & Y \\ CH_3O^* + C_3H_7 + M & \rightarrow & Z \end{array}$$

where M may be any molecule capable of combining with the radicals as indicated to yield the products X, Y or Z, making the radicals CH_3O- and C_3H_7- the active compounds in chain propagation.

Experiments on propane oxidation carried out by Pease and Munro[23] indicated that detectable amounts of a peroxide compound were formed during slow combustion. However, it was found that if the reaction tube was coated on the inside by a thin layer of potassium chloride, the peroxide was almost completely destroyed. Still, the reaction under these peroxide-free conditions was not appreciably slower than that in the clean (i.e., potassium chloride-free) tube.[24]

In conclusion, the work done with photochemical oxidations is of interest in understanding the mechanism of oxidation. Schumacher[25] reports, for instance, that the photochemical oxidation of rubrene indicates that the molecule may undergo fluorescence, stabilization, or direct addition of oxygen, after the absorption of light energy. A stable peroxide can be formed either by addition of oxygen to the stabilized rubrene molecule, or by deactivation of the activated peroxide. In any case, he states, the photochemical oxidation of rubrene represents direct absorption of light energy by the reactant, followed by a non-chain process. On the other hand, the chlorine-sensitized photo-oxidation of methane, methyl chloride and dichloromethane are chain reactions, involving the formation of short-lived peroxides. The first two reactions (i.e., the oxidation of methane and methyl chloride) are markedly inhibited by an excess of oxygen, whereas the oxidation of dichloromethane is not.

EFFECT OF TEMPERATURE ON HYDROCARBON OXIDATION

In the reaction between the normal paraffins and oxygen, there is a fairly sharp spontaneous ignition temperature. Estradere[26] found this temperature of inflammation becomes progressively lower as the number of carbon atoms in the hydrocarbon molecule increases. Working with the normal paraffins from pentane through decane, and the higher homologues dodecane, tetradecane and hexadecane, this worker noted that the temperature of ignition for such hydrocarbons could be related by the expression $T = 192 + 756/n$, where T represents the temperature of ignition in degrees Centigrade, and n the number of carbon atoms in the hydrocarbon molecule. T was experimentally determined in the instances listed above by gradually raising the temperature of a mixture of the hydrocarbon with oxygen until a sudden, sharp rise indicated the ignition of the mixture.

Akita,[27] studying the similar problem of reaction temperatures, determined the "reaction starting temperature" by heating an oxygen-hydrocarbon mixture under constant volume conditions. The temperature at which a sudden abnormal increase in pressure occurred was taken as the point at which oxidation actively started. This investigator reported that for each normal hydrocarbon or alcohol, a series of reaction temperatures could be detected, the number of successive points being equal to the number of carbon atoms in the original molecule. Each succeeding abnormal pressure increase occurred at a temperature slightly higher than that of the preceding pressure rise, and at a temperature corresponding to the "reaction starting temperature" of the next lower normal hydrocarbon. An analogous series of reaction temperatures was detected for each of the normal aliphatic alcohols.

The same type of experimental procedure was applied to the study of the oxidation of aromatic hydrocarbons of the benzene and phenol series, but with these compounds no such series of reaction temperatures could be detected.

Gieb and Harteck[28] have reported a study of very low (liquid air) temperature oxidation reactions. These workers report that additive reactions, in which a stable compound can arise by the increase in valency of an atom of a second stable compound, occur with difficulty. However, addition occurs readily at low temperatures in the case of compounds having unsaturated bonds, or in which the subsidiary (and higher) valence is chemically active. Nevertheless, the union is apt to be so unstable as to form compounds unknown at room temperature. An additive product of ethylene and oxygen was found which decomposed at −110°C. to yield ethylene oxide, formaldehyde, acetaldehyde, carbon dioxide, and other liquid products. A similar treatment of acetylene resulted in carbon monoxide, ethylene glycol, formic acid, carbon dioxide, and water. Carbon monoxide adds oxygen only to a slight degree (1.3 per cent) to form carbon dioxide. Mono- and dimethylamine readily combine with atomic oxygen. At — 80° benzene gives a colorless, glassy material which decomposes into carbon monoxide and dioxide, formic acid and water.

OXIDIZING AGENTS OTHER THAN OXYGEN

Oxygen, particularly that in the atmosphere, has a great economic advantage over any other oxidizing agent, where it is applicable. However, various other oxidizing agents are of importance, especially the oxides of nitrogen. These latter compounds are reported to be useful in many instances as catalytic agents in processes employing air. According to Serbinov and Neiman,[29] the velocity of reaction between oxygen and ethane is increased several-fold by the addition of traces of nitrogen dioxide. Experiments were conducted with the reactants at a temperature somewhat below 500°C. and under 100 mm. pressure. It was found that the reaction velocity was higher, although the autocatalytic character of the normal oxygen-ethane oxidation was eliminated. These investigators did not believe that any direct interaction took place between the nitrogen compound and the hydrocarbon, but rather that the nitrogen oxide served to activate the oxygen present, according to the following series of reactions:

$$\begin{array}{lcll} NO_2^* + O_2 & \longrightarrow & NO_2 + O_2^* & \\ O_2^* + H_3C{-}CH_3 & \longrightarrow & C_2H_6O_2 & \\ O_2^* + O_2 & \longrightarrow & 2O_2 & \text{(chain ends.)} \end{array}$$

They suggest that a chain length of 100 may be possible in the complete reaction. James[30] described a method of oxidizing petroleum products using nitric acid, and the nitrogen oxides produced from it, as catalysts. In an example, he cites using a wax distillate which was atomized and injected into a reaction globe, maintained at 85° to 88°C. Simultaneously, nitric acid (1650 cc. of 70 per cent acid per 1100 cc. of wax distillate) was atomized and injected. The acid was recovered, to the extent of 85 per cent, in the liquids drawn off at the end of the reaction. The recovered oil containing oxidized substances (about 27 per cent of carboxylic acids) represented 95 per cent of the hydrocarbon injected. The operation was carried out at temperatures of 72° to 120°C. The investigator suggests that the mechanism involved the reduction of the nitrogen pentoxide, with oxidation of the hydrocarbon, and the subsequent regeneration of the higher nitrogen oxide by reaction with oxygen of the air. The oxide of nitrogen thus acts more in the rôle of carrier than catalyst.

Platonov and Shaikind,[31] however, investigated the oxidation of various hydrocarbons using nitric oxide as the oxidizing agent, rather than as a catalyst. In these experiments propane, hexane and heptane as well as gasoline (boiling from 63° to 77°C.) vapors were passed over catalysts in ratios from 1:1 to 1:3.5 with nitrogen monoxide. Various mixtures of aluminum, cerium and thorium oxides were used as catalysts (with and without carriers), also platinum black and vanadium pentoxide deposited on ceramic rings. When the milder catalysts (aluminum, cerium and thorium oxides) were employed, there were found some primary

nitro compounds, sometimes primary amines, and considerable amounts of ammonium carbonate mixed with ammonium nitrate and nitrite in the products. A small proportion of the hydrocarbon was decomposed, forming unsaturated compounds and carbon dioxide. The ammonium carbonate is evidently the result of the union of ammonia (from the reduction of nitrogen monoxide) with water and carbon dioxide (from the oxidation of the hydrocarbons). The mechanism of the formation of the nitrates and nitrites was not clear, however, since air was excluded from the reaction zone. Employment of platinum and vanadium-pentoxide catalysts gave no organic nitrogen compounds, the chief products consisting of carbon monoxide, carbon dioxide, water, and free nitrogen, while most of the hydrocarbon remained unchanged. In none of the experimental runs was there any noticeable formation of organic acids, while nearly 30 per cent of the hydrocarbon was burned to carbon dioxide and water, with a considerable production of unsaturated compounds accounting for a major portion of the remainder. Addition of water vapor to the reactants increased thermal decomposition of the hydrocarbons without increase in the formation of organic acids. On the other hand, it has been reported[32] that the oxidation of hydrocarbon gas with nitrogen oxides may be controlled to yield hydrocyanic acid. High temperatures are needed, it is said, temperatures in the range of 1200° to 1400°C. being recommended. The mixed hydrocarbon and nitrogen oxides, together with a diluent such as nitrogen, carbon monoxide, or water is passed over platinum, platinum-rhodium or platinum-palladium catalyst at a temperature between 800° and 1400°C. but best between 1200° and 1400°C., as previously mentioned.

Steacie and McDonald[33] investigated the reactions involved when nitrous oxide (N_2O) was used as the oxidizing atmosphere in place of oxygen. Tests were made with methyl alcohol, ethylene, acetaldehyde, phosphine and carbon disulphide. Their results indicated uniformly higher ignition temperatures in the nitrous oxide atmosphere than in oxygen. With ethylene, the oxygen atmosphere reacts at a measureable rate at 300° to 450°C. On the other hand, nitrous oxide-ethylene mixtures interact only slowly at 530°C. With methyl alcohol, too, nitrous oxide reacts only at a much higher temperature (500° to 750°C.) than is required for the oxygen-methanol reaction. The temperatures required for acetaldehyde oxidation were even more widely separated. This aldehyde reacts with oxygen at 60° to 120°C., but with nitrous oxide a temperature of 450°C. was required. In the latter instance a very appreciable portion of the acetaldehyde disappearing was not oxidized, but thermally decomposed.

Various organic nitro compounds also serve as oxidants in certain reactions. Martin and Fletcher[34] report that aromatic nitro compounds such as the nitrobenzoic acids, nitrobromobenzenes and nitroanilines, for instance, will oxidize benzyl alcohol to benzoic acid, the yield varying with the temperature, alkalinity and nature of the nitro compound employed. The latter was, in no case, reduced to the primary amine. Either the azo, azoxy or hydrazo compound resulted. Zhukov[35] suggested using the salt-like bodies formed by aldehydes and ketones with nitric acid as oxidizing agents. Such bodies are obtained by dissolving the particular oxygenated compound chosen (e.g., camphor, menthone, cinnamic aldehyde) in strong nitric acid, slightly more than one molecular proportion of the acid being employed. The solution is cooled, and the crystalline precipitate separated. To effect oxidation, the organic compound to be treated is dissolved in the (molten) nitrate thus obtained, and the mixture allowed to react for some time at ordinary temperatures. The products are recovered by washing with water to separate the freed nitric acid.

Hydrogen peroxide has been an important oxidizing agent, and may frequently be used in studying the constitution of an organic compound by oxidation. Giacomello and Mascarello[36] investigated the oxidation of the lower aliphatic acids in this way, and report that reaction takes place in several stages, with ultimate formation of carbon dioxide. The radicals liberated from the functional carbon atom which forms carbon dioxide, either form hydrocarbons or repeat the cycle with oxidation to alcohols, aldehydes and acids. Dupont and Dulou[37] report oxidizing cyclohexene in an ether solution of hydrogen peroxide, using osmic tetroxide as catalyst. In anhydrous ether, the reaction is very slow, the investigators state, and the products consist largely of acetaldehyde and acetic acid. The solvent is more readily oxidized than the cyclohexene. However, in methanol, ethanol, butanol or benzene solutions, cyclohexene is easily oxidized to cyclohexanediol.

The activity of ozone as an oxidizing agent is well known but, according to Briner and Carceller[38] it can act also as a catalyst in bringing about oxidation. Below 150°C. butane and pentane are oxidized to a very slight extent by oxygen, though in the presence of ozone appreciable proportions of aldehydes and acids are formed. At higher temperatures, ozone appears to function catalytically to bring about combination of the hydrocarbon with oxygen in the diatomic state. When ozone is not present, a certain amount of oxygen is found fixed in the recovered oxidation products. With ozone present (under conditions otherwise identical) the quantity of combined oxygen is greater than that represented by the ozone consumed plus the amount that would have been fixed had no ozone been present. This difference was taken to represent diatomic oxygen which had been brought into combination by the catalytic activity of the ozone.

Perhaps selenium dioxide is one of the most interesting of the other oxidizing agents used. It displays peculiar selectivity in its oxidation reactions, in some cases attacking unsaturated compounds at saturated carbon atoms once, and even two successive times, without affecting the double bond.[39] This dioxide is a relatively vigorous oxidizing agent, according to Astin, Moulds and Riley,[40] particularly at high temperatures, and it is therefore somewhat surprising that unstable, highly reactive compounds such as mesoxalic ester and ketohydrosuccinic ester can be prepared through its agency. Intermediate compounds may form an important part in the mechanism, and in support of this view unstable organoselenium compounds have been isolated. However, the investigators mentioned believe that the explanation is to be found in the reactions of the selenium atom itself, rather than in the oxide molecule. One peculiar manifestation of the oxidizing powers of this selenium oxide is displayed by flames being propagated in an atmosphere of selenium dioxide vapor. Ammonia, carbon disulphide, hydrogen sulphide and a large number of organic compounds burned in this way all give flames producing similar spectra which are characteristic of selenium and selenium dioxide, but not of the compounds undergoing oxidation. This phenomenon, it was believed, indicates that the selenium compound possesses the property of providing compounds undergoing combustion with oxygen atoms in a very low energy state. If the dioxide retains this property at lower temperatures (e.g., those temperature ranges in which it displays its specific oxidizing reactivity) then it is understandable that certain unstable compounds can be formed. As an example of this selectivity, Riley[41] reports that selenium dioxide will oxidize a methyl group adjacent to a carbonyl group. Thus, pyruvic aldehyde may be produced from acetone, or, hydrated phenyl glyoxal may be obtained from acetophenone:

Electrolytic oxidation of hydrocarbons has been difficult, and not generally attended by great success, since the hydrocarbons are not electrolytes, and must be emulsified with an electrolyte. However, a suggestion made by Hultman[42] offers an indirect electrolytic method which is said to overcome this difficulty. The investigator proposes that an apparatus be constructed holding sulphuric acid in a lower chamber, and hydrocarbon in the upper chamber. In the lower chamber a platinum anode (water cooled) is set under a glass cup, or funnel, which is carried on a tube running up through a division membrane to the upper chamber. A lead sheet surrounding the anode and inverted cup serves as cathode. On passing current between the electrolytic poles, the release of active oxygen at the anode serves to produce various highly oxidized sulphur acids, such as persulphuric acid, Caro's acid, as well as forming free oxygen, some ozone, and hydrogen peroxide. The release of the free gases causes a vigorous bubbling in the confined region under the glass cup, and the rising bubbles carry the highly oxidized acids with them, into the hydrocarbon chamber. A vigorous action is reported to take place here, giving the appearance of rapid boiling. The spent acid settles back through the hydrocarbon to a pipe which permits its return to the electrolyzing chamber below. (See Fig. 198.)

By means of the water-cooling coils, the temperature of the electrolyte is maintained near 23°C. According to Hultman, under these conditions vigorous oxidation results, but the low temperatures permit the stability and recovery of the products. Saturated compounds can be oxidized in this manner to acids, alcohols, aldehydes and ketones. Unsaturated hydrocarbons yield either similar compounds, or glycols and their oxidation products. For example, a petroleum ether (uncracked) consisting largely of pentane, hexane and heptane was oxidized by this method, and at the end of three to five minutes, the product contained butyl, amyl, hexyl and heptyl alcohols. After running for 10 to 15 minutes, the corresponding aldehydes were reported to be present in the electrolyte in considerable amount. After half an hour, fatty acids corresponding to these hydrocarbons were found in about 5 per cent concentration. When a cracked petroleum ether (boiling from about 40° to 70°C.) was used as the starting material, dihydric alcohols were produced. Continued oxidation yielded aldehydes and acids of a lower number of carbon atoms. A cracked gasoline furnished butyric and higher acids as well as higher glycols and their oxidation products. Hultman reports that catalysts, such as cerium sulphate, may be employed in addition to the electrolyte. It was further pointed out that the necessary factor in this method is that there be the shortest possible time interval between the production and utilization of the highly oxidized sulphuric acids. A mixture of sulphuric and persulphuric acids (made by reacting potassium persulphate and sulphuric acid) is practically ineffective.

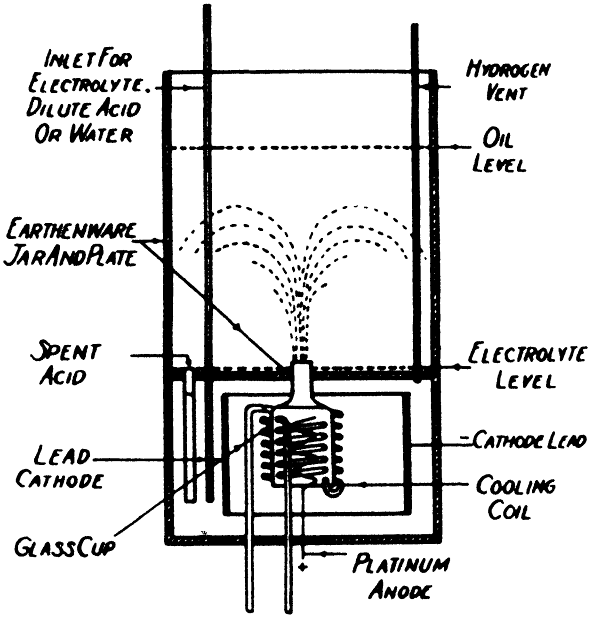

FIG. 198. Apparatus for Electrolytic Oxidation of Liquid Hydrocarbons. (E. W. Hultman)

PEROXIDES IN GASOLINES AND OILS

Although it has not been shown that the peroxides of the lower hydrocarbons can be isolated, the naphthenes and higher olefins do form comparatively stable peroxides. These latter compounds are generally powerful oxidizing agents, and serve to bring about the formation of gums and colored substances in gasoline and oils.[43] The naphthenes appear to be particularly prone to give peroxides, some of which are sufficiently stable to be concentrated to a considerable degree. Thus, Ivanov[44] reports oxidizing cyclohexane in the vapor phase at 316° to 370°C., in the presence of air, to an extent that yielded 6.5 grams of crude peroxide from 25.5 grams of cyclohexane. This required about ten hours. The crude product decomposed very rapidly on standing at room temperature, in the presence of light, to give about 52 per cent active oxygen. It could not be distilled (under 2 mm. pressure of nitrogen, at a maximum temperature of 170°C.) without decomposition. However, it was possible to remove volatile impurities, and water, by subjecting the crude product to 3 mm. pressure. The purified product was more stable, and released a greater proportion of active oxygen. By fractionation with diethyl ether, the material was separated into two substances. Analyses and molecular weight determinations indicated the empirical formula $C_7H_{14}O_7$ for the soluble fraction, and $C_7H_{14}O_6$ for the insoluble portion. These compounds were believed to be $(HOO)_2C_6H_9OOCH_2OH$ and $HOOC_6H_9(OH)OOCH_2OH$, respectively, from their reactions. It was thought that they resulted from the condensation of formaldehyde (formed during oxidation) with a peroxide of the formula $C_6H_9(OOH)_3$.

---

Candea and Cristodulo[45] studied the oxidation of a light gasoline derived from a Rumanian Moreni crude oil, and compared the products obtained with those derived from the oxidation of pure cyclohexane, pinene, benzene, and mixtures of hydrocarbon fractions extracted from the original oil. Cyclohexane, and especially pinene, promoted the formation of peroxides at 320°C., while the aromatics were not only harder to oxidize, but retarded the development of peroxides. Oxidation of the pinene gave rise to gummy materials. The conclusion that naphthenes generally promoted peroxide formation (as did also pinene) while benzene and aromatics minimized this reaction appears to be confirmed by the work of Chernozhukov and Krein[46] with heavier hydrocarbon materials. These investigators worked with lubricating oils, and reported that an oil containing naphthenes and 15 to 20 per cent of aromatic hydrocarbons with paraffin side-chains formed no precipitate on oxidation, though the acid content increased due to oxidation of the side chains. In such material, the course of oxidation is the same as in the absence of naphthenes. However, if less than 10 per cent of aromatics is present, oxidation proceeds as in the case of purely naphthenic material. When an oil contained as much as 5 per cent of hydrogenated aromatic hydrocarbons, a precipitate formed on oxidation. The latter was found to consist largely of hydroxy acids, asphaltenes and carbenes. At higher concentrations of the hydrogenated aromatics, the insoluble bodies are almost entirely hydroxy acids. Aromatic tarry substances did not affect the oxidation, although naphthene-tars accelerated it.

It is believed by many investigators that the cause of autoxidation is to be found in the production of active peroxide substances. This autoxidation is a problem of considerable industrial importance, as it affects the storage of gasoline, the reactions of lubricating oils, the aging of rubber, gum deposition, and in many other ways affects the handling and usage of hydrocarbon materials. Autoxidation can be to a large extent controlled by the use of antioxidants, the choice of which being directed by the conditions under which it must serve. Dufraisse[47] has shown the antioxidant effect of an ether solution of hydroquinone on an unsaturated material such as sheet rubber. If one portion of a sheet of this material is dipped into the ether solution, and another portion is not, natural aging will harden the undipped portion, making it brittle and friable, while the dipped portion, protected by the antioxidant, remains pliable.[48] Lederer[49] has derived equations representing the rate of oxidation on either of two proposed mechanisms; that involving the absorption of an atom of oxygen, and that in which a molecule of oxygen is absorbed with the formation of a peroxide. The plot of time versus oxygen absorbed should, on purely theoretical grounds, be parabolic in the first case, and sigmoid in the second type of reaction. Experimental work indicated that reactions of the second type (peroxide formation) occur as the main ones with compounds containing two or more double bonds, and an active hydroxy or carboxy group, or a branched chain. Aromatic compounds with alkyl side chains possessing these characteristics react in a similar manner. In general, the reaction coefficient increases with increasing molecular weight, and the terpenes show the highest reaction rate of any hydrocarbons. A knowledge of oxidation characteristics is important in evaluation of transformer and lubricating oils, but determinations of the reaction velocities are cumbersome and unsatisfactory. It is usually sufficient to determine the "oxidation number," i.e., the amount of oxygen which one gram of oil will absorb in 100 minutes at 100°C., since in almost all cases the oxygen absorbed-time curve is nearly linear.

Of the various types of mineral oils, the super-refined mineral white oils absorb most oxygen at 110°C., according to Muller.[50] Tests were made on various transformer oils at this temperature during periods up to 500 hours, though most of the tests were concluded at the end of 400 hours. It was found that the white oils absorbed by far the largest quantity of oxygen (400 to 10,000 cc. per 100 cc. of oil), the partially refined oils absorbed least, approximately 70 to 170 cc. per 100 cc. of oil, with the slightly refined oils intermediate, absorbing 100 to 250 cc. per 100 cc. The addition of a catalyst (copper stearate) increased the absorption in the latter two oils, but had little effect on the white oil. The products at the end of 400 hours consisted (in order of decreasing amount) of water, non-volatile saponified matter, ketones, fixed acidity, alcohols, and volatile acidity. Though peroxides formed in the early stages of the oxidation, at the end of the test period (when the oil was cooled) none was found.

THE TECHNICAL OXIDATION OF HYDROCARBONS

General Considerations. In technical processes for the partial oxidation of hydrocarbons, air or oxygen is most widely used as the source of oxygen, and natural or cracking gases frequently furnish the hydrocarbon material. Oxidation of the high molecular weight hydrocarbons of paraffin wax to carboxylic acids has attracted considerable attention. Perhaps because of the extreme difficulty of separating the complex compounds produced, petroleum hydrocarbons of the middle range (fuel oil and higher) have attracted somewhat less interest heretofore.

As Newitt and Townend[51] have pointed out, both natural and cracking gases contain upwards of 80 per cent of paraffin hydrocarbons, chiefly methane and ethane, with smaller proportions of olefins, higher paraffins, hydrogen, carbon dioxide and nitrogen. The enormous quantities of these gases available make them an attractive source of oxygenated compounds. That such operations can be economic is indicated by the work of these investigators on oxidizing ethane at 272°C. under 100 atmospheres pressure. Over 71 per cent of the carbon of the ethane consumed was found in the condensed products, which had the following composition:

[50] G. Muller, *Compt. rend.*, 1935, **200**, 1769; *Chem. Abs.*, 1935, **29**, 5255; *Brit. Chem. Abs.*, **B**, 1935, 709.

Ethyl alcohol.....	51.0 Per Cent
Methyl alcohol....	28.0
Acetaldehyde.....	11.1
Acetic acid.......	9.0
Formaldehyde....	0.3
Formic acid.	0.6
	100.0

The principal considerations involved in technical partial oxidations of these hydrocarbons are the necessity for rigid heat control and the danger of explosive mixtures.[52] At room temperature and atmospheric pressure, mixtures of oxygen and methane containing between 6 and 58 per cent of the latter are explosive. At the higher temperatures employed in slow combustion these limits are further widened. The control of the temperature of the reaction must also take into consideration the great amounts of heat liberated according to the following equations:

$$2CH_4 + O_2 \longrightarrow 2CH_3OH + 2 \times 29{,}730 \text{ calories.}$$
$$2CH_3OH + O_2 \longrightarrow 2CH_2O + 2H_2O + 2 \times 20{,}640 \text{ calories.}$$
$$2CH_2O + O_2 \longrightarrow 2HCOOH + 2 \times 81{,}540 \text{ calories.}$$

Since the formation of methyl alcohol and formic acid (from methane and oxygen) results in a decrease in volume, and that of formaldehyde is accompanied by an increase in volume, increasing the pressure tends to displace the equilibrium in favor of the alcohol and the acid. High temperatures accelerate all three reactions and lead to complete oxidation to carbon dioxide and water. Hence, temperatures as low as possible, with high pressures, favor the development and stability of the alcohol. From the kinetic standpoint, high pressures would tend to accelerate the reactions, as would high temperatures. A certain degree of heat would be necessary to cause the reaction velocity to reach a practicable value, but the temperature must then be limited fairly closely. This effect may be obtained in a number of ways, but the use of high space velocities in the reaction chamber is, perhaps, one of the simplest.

Due to the close relationship between temperature and pressure in reactions of this type, the investigators could not entirely separate the effect of the two factors. Therefore, in studying the effects of pressure, a wide range was tested, employing in each case a temperature previously ascertained as the optimum for obtaining liquid products. The results so obtained (see Table 175) indicated the result of employing increased pressure.

TABLE 175.—*Effect of Pressure on Liquid Product Yield.*

Initial Pressure (Atmospheres)	Reaction Temperature °C.	Liquid Products in Per Cent of Carbon of Hydrocarbon Consumed	
		$81CH_4 + 10O_2$	$88.4C_2H_6 + 11.6O_2$
10	400	1.1	—
15	315	—	41.8

75	279	—	46.0
100	270.5	—	50.4
149	341	19.6	

The experiments conducted in the circulatory system unit generally confirmed the results obtained statically. Thus, with the 10 per cent oxygen concentration in ethane, at 260 to 270°C., under 50 atmospheres pressure, the reaction took place slowly. A yield of a clear, water-soluble condensate containing 70 per cent of alcohols, and 20 per cent of aldehydes, with small quantities of acetic and formic acids resulted. By varying the rate of circulation, the ratio of methyl to ethyl alcohol could be varied between comparatively wide limits, although the total aldehydes and acids remained comparatively constant.

---

[52] See Chapter 44.

Wiezevich and Frolich[53] reported an extended study of the partial oxidation of the saturated hydrocarbons of natural gas. It was found that methane (from natural gas) reacted with oxygen at temperatures near 500°C., though at higher temperatures, the tendency was toward the production of carbon oxides, rather than oxygenated derivatives. Of the products formed, methanol was present in preponderance, generally in quantities three to eight times the amount of formaldehyde. Some formic acid was produced as well as considerable amounts of water.

Since propane is liquid at normal temperatures at the high pressures employed, advantage was taken of the fact that oxygen is relatively soluble in the liquid propane. By saturating the liquid with air, an automatic control of the oxygen-hydrocarbon ratio below the explosive limit was maintained. Experiments indicated that the ideal conditions for the production of alcohols from propane were pressures above 130 atmospheres (up to 200 atmospheres, though higher pressures did not increase the formation of alcohols to a noteworthy extent), temperatures as low as practicable, time of reaction under 10 seconds, and oxygen concentration as high as the limits of explosiveness permitted. A representative reaction at 350°C. under 170 atmospheres pressure, in a steel tube, using 7.9 per cent oxygen concentration gave the results shown in Table 176.

TABLE 176.—*Oxidation Products of Propane.*

Product	Per Cent of Oxygen Converted to Compounds

Carbon Dioxide	10.1
Carbon Monoxide	9.7
Water	30.7
Unconverted oxygen	7.0

Variation of the propane-oxygen reaction with pressure was studied in a reactor immersed in a lead bath. A 6 per cent oxygen concentration and a long contact time were employed. The results showed that increase in pressure lowers the temperature at which appreciable reaction occurs. (See Table 177.)

TABLE 177.—*Variation of Propane-Oxygen Reaction Temperature with Pressure.*

Pressure Atmospheres	Reaction Temperature °C.
150	112.8
67	143.8
53	151.7

A circulatory flow system was developed for the production of acids from propane, the apparatus being so arranged that the acids were removed by neutralization, and the remaining products recirculated until they too were converted to acids. The propane-oxygen mixture was reacted at 400°C., then passed to a neutralizer and separator. The non-acidic products, and unreacted hydrocarbon, were returned for further reaction. The yields, in terms of liters per thousand liters of liquid propane, per pass were:

---

[53] P. J. Wiezevich and P. K. Frolich, *Ind. Eng. Chem.*, 1934, **26**, 267; *Chem. Abs.*, 1934, **28**, 2249; *Brit. Chem. Abs.* **B**, 1934, 491.

Acetic acid	1.5
Formic acid	1.1
Intermediate products (remaining in system after run)	8.0
Formaldehyde	0.4
Propane lost as CO and CO_2	7.0
Water	9.5

Work with butane indicated that the reaction temperature varied with pressure in a manner similar to that of the propane-oxygen reaction. Further, the higher pressures used favored the production of higher, rather than lower, molecular weight alcohols and acids. As with propane, an acid-production run was made, recirculating the products for further oxidation to acids. In the case of butane, somewhat higher yields (3.62 liters per thousand liters of liquid butane per pass) of acetic acid were reported, and a lower (0.62) yield of formic acid. It was found, however, that increasing the isobutane content of the gas increased the formation of formic acid.

With pentane, oxidation under generally similar conditions gave somewhat better yields of higher alcohols, Wiezevich and Frolich reported. The products boiling from 80° to 110°C. consisted mainly of a mixture of ethyl and propyl alcohols. The higher alcohols were largely *sec*-amyl with small amounts of *ter*-amyl. The pentane consumption indicated a ratio of liters of pentane consumed to liters of product of 1.7:1. The run made with recycling of all products, except acids, changed the ratio of acids produced from 98 parts acetic to 2 of formic (found in the unrecycled product) to the following composition:

Acid	Per Cent by Volume
Formic	20
Acetic	53
Propionic	14
Higher	13

About 7 liters of acid were produced per 1000 liters of pentane per pass, while the loss to carbon dioxide and monoxide amounted to about 0.2 per cent of the pentane per pass.

Since the main products of the oxidation of pentane contained 2 or 3 carbon atoms per molecule, it was believed that the oxidation of heptane might lead to the production of 5 carbon compounds, such as amyl alcohols. The heptane used was a light gasoline fraction boiling between 70 and 97°C., containing all the heptane isomers present in casinghead gasoline. With this heavier hydrocarbon, longer contact times were needed. The operation was carried out at 225°C. under 135 atmospheres pressure (and hence presumably in the liquid phase). The products actually obtained were found to consist largely of alcohols in the heptyl-hexyl range, boiling between 140 and 180°C.

Klatt and Jellinek[54] have investigated the oxidation of kerosene, using a naphthene-base Russian oil, to produce the maximum of water-soluble compounds. No attempt was made to isolate the component hydrocarbons in this petroleum fraction. Manganese dioxide and vanadium pentoxide were tried as catalysts at temperatures ranging from 250 to 500°C. It was found that the manganese

[54] R. Klatt and H. Jellinek, *Petroleum Z.*, 1934, **30**, No. 12, 1; *Chem. Abs.*, 1934, **28**, 4883; *Brit. Chem. Abs.* **B**, 1934, 438. Also *Refiner*, 1936, **15**, 183; *J. Inst. Pet. Tech.*, 1936, **22**, 357A.

catalyst induced considerable pyrolysis. Vanadium pentoxide had a favorable effect on acid formation, improving with use. Reaction tubes of various types were tried, such as a copper tube packed with aluminum foil or turnings. In this case, acid-reacting substances were formed which were insoluble in water. It was concluded, however, that the most satisfactory arrangement of apparatus included a metal reaction tube, vanadium pentoxide catalyst, and diluent gases in the stream of reactants. Steam and nitrogen were used as diluents, and the amount and character of the yield were influenced to some extent by the proportion of diluents. The use of steam tended to inhibit secondary reactions, and very rapid cooling after passing the reaction zone aided in suppressing undesirable changes. The best method of vaporizing the kerosene was found to consist in dropping the oil on hot glass wool or pumice. Using 5 per cent vanadic oxide catalyst on pumice, at 440°C., about 7.5 per cent of converted material was obtained. The ratio of water to kerosene vaporized was 3 to 1. The reaction product so produced consisted of a water-soluble, yellow-brown material, highly acidic and pungent. A heavy white precipitate was formed at the oil-water interface consisting apparently of solid, carboxylic acids. It was impossible to characterize individual compounds in these products, but in certain cuts the presence of formic and acetic acids, formaldehyde, acetaldehyde and acetone was demonstrated.

In oxidizing the heavy hydrocarbons of paraffin wax, even lower temperatures are practicable. Burwell[55] reports that these heavy hydrocarbons may be oxidized in the liquid phase at temperatures in the range of 120 to 180°C., with or without a catalyst. With air, pressures of 200 to 500 pounds per square inch are employed; with oxygen, 150 to 250 pounds per square inch is sufficient. It was found that in the absence of catalysts, the straight-chain compounds were more readily attacked than other types. Under the mild temperature conditions indicated, the end (or methyl) group of the hydrocarbon is not attacked, but the reaction seems to involve primarily the second or third carbon of the chain, causing scission at the point of attack. (See also Chapter 43.)

Since oxidations are strongly exothermic reactions, in general, and are, as has been indicated, sensitive to temperature change, accurate control of the temperatures involved in the reactions is both necessary and difficult. In certain cases the cheapest of all heat-transfer media, water, is practicable, but in many instances the reactions must be carried out at temperatures above the critical for water.

Wiezevich and Frolich[56] used a number of different heat-transfer media while working on the oxidation of pentane, some for preheating the entering gas, and some for heat-transfer systems controlling the reactor temperature. Pentane was preheated to a temperature of 180°C. in a steel tube immersed in boiling naphthalene. The vapors were then passed into a steel reactor kept at about 240°C. by a boiling diphenyl oxide bath. At this point a small stream of pentane superheated to about 550°C. by a lead bath was injected, serving to start the reaction. Although the molten lead bath served as a heat reservoir for stabilizing temperature to some extent, it was somewhat handicapped where large quantities of heat were concerned at such a temperature as this (550°C.) because of its low specific heat. Transition temperatures (e.g., melting point, boiling point) were generally employed, since large quantities of heat may then be absorbed without change in temperature. Thus for cooling the reactor itself, where the highly exothermic reaction was taking place, the latent heat of vaporization of diphenyl oxide was employed as a controlling agent The latent heat of volatilization of various substances may be employed, or the latent heat of fusion of eutectics may be used.[57] Evidently the latent heat of vaporization is advantageous in that temperature may be controlled over some range by the application of pressure, while it may be accurately held at a chosen temperature by the large thermal capacity of the volatilization of the heat absorbing agent. Either elements such as mercury, or sulphur,[58] or compounds such as the aryl ethers, for instance diphenyl, naphthyl phenyl, or hydroquinone phenyl ether, may be used for this purpose.[59]

Egloff[60] suggests the rate of the reaction may be controlled chemically, by the addition of certain substances, such as tetraethyl lead. This method is applicable, for instance, in the oxidation of petroleum products (in the gasoline range) to alcohols, aldehydes and acids. Less than one per cent of the lead compound need be used, and the reaction may be carried out at 600°C.

Another problem is the separation of the complex mixtures of oxidation products. Those resulting from the treatment of hydrocarbons in the intermediate or fuel oil range of petroleum distillates become so complex that fractional distillation is frequently exceedingly difficult. It has been suggested that the reacted gases be conducted over a series of oil layers containing oxidation products and maintained at different temperatures. In this way, it is reported, fractional condensation of the various oxygen-containing compounds is obtained.[61] James[62] recommended a solvent process, using liquid sulphur dioxide to extract the more-highly oxidized bodies. The operation is carried out at a temperature of —18 or —20°C., and the products are separated by further cooling at —45°C. Sulphur dioxide may be recovered by evaporation.

Oxidation in the Vapor Phase. In processes devised for obtaining oxidation products from hydrocarbons, both vapor- and liquid-phase methods have been mentioned, and it will be recalled that the progress of oxidation appears to differ in the two modes. It is evident that inasmuch as a large percentage of such operations are carried out at elevated temperatures, using hydrocarbons of low carbon atom number, these reactions may take place in the vapor phase. As pointed out previously, the oxides of metals of variable valence (such as vanadium pentoxide) are frequently employed as contact agents. However, methods involving catalysts such as the lower alkyl ethers have been suggested. Burke and Fryling[63] report that dimethyl or diethyl ether acts effectively in this capacity. In an example, liquid propane and diethyl ether were mixed (in proportions such as to yield 0.8 per cent ether in the vapors), and vaporized. The gases were then mixed with sufficient air to give 5.9 per cent oxygen in the resulting mixture. The gas mixture, under a pressure of 750 pounds per square inch, was passed through an aluminum-lined reaction tube 1/16 of an inch in inside diameter, and 20 inches in length. A flow of 15½ cubic feet of gas per hour was maintained through the tube, which was immersed in a bath of fused sodium and potassium nitrates kept at 350°C. (Contact time under these conditions was 0.185 second.) The products were immediately, and rapidly, chilled on leaving the reaction zone, and the liquid portion collected. The latter consisted of water, methanol, formaldehyde, acetaldehyde, together with higher alcohols, aldehydes, acids and ketones. This process is said to be quite sensitive to conditions of preheat. When the reactants were first heated to 357°C., the average molecular weight of the condensable products was 38.2. With a preheat of 370°C., the average molecular weight fell to 33.7. Using a lean natural gas (containing over 85 per cent methane), dimethyl ether as catalyst, and increasing the reaction temperature to 450°C., the products were methanol and formaldehyde. It was reported that yields approximately three times as great were obtained when employing the ether catalyst, as compared to those obtained without catalyst.

Burke[64] has proposed a method based on the fact that the temperature of reaction of a mixture of gaseous hydrocarbon and oxygen or air is lower in a tube of large diameter than in one of small diameter. In his process the reactants are heated to the proper temperature in a small diameter tube from which they emerge into a large chamber where reaction commences at once. He points out that in this manner it is possible to limit the zone of interaction to a relatively small volume and thus minimize changes in pressure and resultant fluctuations in the process. From the enlarged compartment the gases pass to small tubes, where efficient and rapid cooling is possible, bringing about a rapid extinction of the reaction. As an example, propane was vaporized and heated to 150°C., and the vapor mixed with air sufficient to give a 6.15 per cent oxygen concentration. Under a pressure of 750 pounds per square inch, the gases were passed through a 51 inch length of steel tube of 1/32 inch internal diameter. During this passage, the temperature was raised to 339°C. However, no reaction occurred under the conditions prevailing. The reactants were then conducted into a reaction zone having an internal diameter of 13/32 inch. and an internal length of 13/32 inch. The gases flowed at a rate of 15.4 cubic feet per hour, giving a reaction time of approximately 0.33 second, after which they again entered into a 1/32 inch steel tube, which extinguished the action. The products consisted largely of methanol, formaldehyde and other higher alcohols, aldehydes and acids.

Bludworth[65] reports that the oxidation of butane can be more accurately controlled by a method involving many recyclings of the reactants while a very small proportion of the ultimate oxidation to be obtained takes place at each pass. The latter condition is secured by using a very limited quantity of air at each pass. This investigator states that a maximum yield of methanol, acetone and acetaldehyde may be procured by this method. As an illustration, if an ultimate yield of eight gallons of liquid product is to be produced from 1000 cubic feet of butane, Bludworth recommends that not more than 0.0005 gallon be produced per cubic foot of butane per pass. He states that there should be not more than 1.25 per cent of oxygen in the reaction zone at any time, nor less than 0.4 per cent. By recycling the gases, fifteen or more times, introducing only a small fraction of the required oxygen in any one pass, interaction is controlled to prevent over-oxidation. Condensable liquids (methanol, acetone and acetaldehyde) are extracted from the gases after each passage through the reaction zone. In practice, about 96 per cent recycle and four per cent fresh butane (or propane) is used. The products then consist of about 8 gallons of methanol (75 per cent), acetone (12.5 per cent) and acetaldehyde (12.5 per cent).

Another method of controlled oxidation is to dilute the reactants with an inert gas, e.g., nitrogen. One procedure consists in cycling a quantity of inert gas in a closed ring system and introducing into this a hydrocarbon-air mixture, subsequently passing the commingled gases through a heated reaction zone and thence to a condenser to remove oxidation products by condensation.[65a] Excess inert gases are vented from the system and the remainder are returned to repeat the cycle. (See Fig. 200.)

Oxidation of gas oil in the vapor phase has been described by James.[66] In this case, vanadium, uranium or molybdenum oxides were used as catalysts. These were deposited on a screen of asbestos, through which the oil vapors, mixed with air, were passed. In one instance, a contact agent consisting of the "blue oxides" of molybdenum was used, coated on an asbestos screen one centimeter thick, and 4.4 centimeters in diameter. The gas oil was a fraction distilling around 275°C. Approximately 125 cc. of the liquid was volatilized and fed into the reaction zone each hour together with 1.6 times the quantity of air theoretically needed for the formation of aldehyde fatty acids. The catalyst was maintained at 270°C. during the run, and the rate of flow was such as to allow 0.32 second contact time. Tests of the exit gases showed 2.4 per cent of carbon dioxide and 1 per cent of oxygen escaping unchanged. At the end of one hour and 35 minutes, 150 cubic centimeters of liquid oxidation products had been recovered, consisting of about 85 per cent aldehyde fatty acids, and 15 per cent mixed aldehydes and unchanged hydrocarbons.

Ellis[67] pointed out that the antiknock value of a gasoline can be considerably increased by subjecting it to partial oxidation. The suggested process involves transfer of the hot hydrocarbon vapors (from a cracking operation) into a long flue-like reaction chamber into which air is admitted at a number of points. The fuel vapors taken directly from the cracking zone are still hot enough to react readily with oxygen, thus eliminating the need of preheating. Since oxidation is exothermic, Ellis recommends that the reaction chamber be cooled by heat exchange with raw oil passing to the cracking unit. In this manner the temperature can be maintained between 120° and 250°C. Pressures of 250 to 350 pounds per square inch are employed. The resultant product is found to be enriched in aromatic content, and contains various partial oxidation products having antiknock properties.[68]

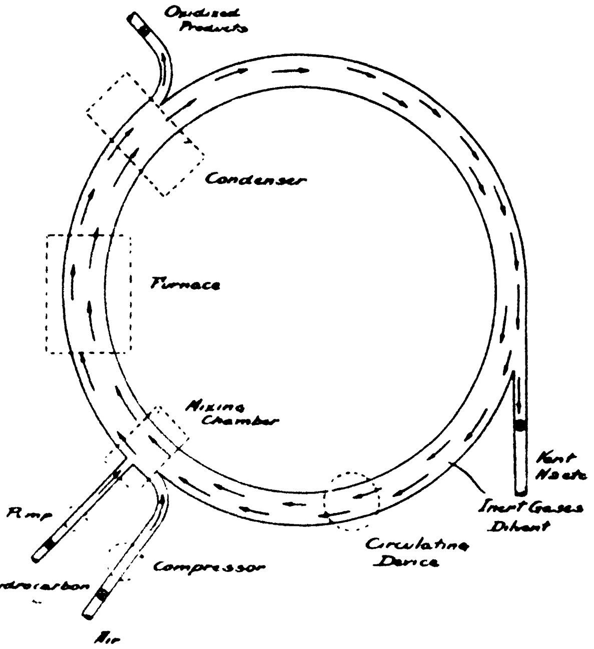

FIG. 200.—Schematic Diagram of Method for Partial Oxidation of Gaseous Hydrocarbons. (J. E. Bludworth, O. R. Sweeney and F. C. Vilbrandt)

Oxidation in the Liquid Phase. As previously mentioned, Wiezevich and Frolich[69] found that oxidation of pentane in the gaseous phase yielded largely propyl alcohol. This appeared to indicate degradation of the hydrocarbon molecule by the elimination of two carbon atoms. By analogy, it was thought that oxidation of heptane would yield amyl alcohols. Experiment showed, on the other hand, that the principal products were alcohols of the hexyl-heptyl range. It was suggested that the difference in behavior, under the conditions of oxidation, could be attributed to pentane reacting in the gas phase and heptane in the liquid phase. It appears then, that liquid-phase oxidations do not follow the course pursued by gas-phase operation. Further, certain other considerations must be taken into account in liquid-phase oxidation. Thus, for instance, it is frequently the practice to bubble the oxidizing gas (e.g., air) through the liquid hydrocarbon. If not all the oxygen is consumed, there may be an accumulation of the gas above the surface of the liquid, mixed with vapors from the hydrocarbon, which may lead to the formation of a dangerous explosive mixture. Penniman[70] suggests that this condition may be prevented by bubbling air through a depth (3 feet or more) of liquid hydrocarbon sufficient to completely deoxygenate it. This treatment is effected under superatmospheric pressure at 320° to 480°C. The liquid condensate obtained from this operation separates into two layers. The upper layer of oily material may be refined for use as an antiknock motor fuel, paint thinners, kerosenes, or similar products. The lower layer is an aqueous solution of organic compounds such as aldehydes, acids and alcohols. Penniman[71] proposed oxidation in the liquid phase at about 400°C., while the vapors produced are continuously withdrawn. Air is introduced into the liquid, and the volatile products formed are removed. From these the less volatile constituents are condensed and the resulting hot condensate is returned to the reaction vessel without further heating. The vapors are fractionated to yield motor fuel, alcohols, aldehydes, ketones and fatty acids.

[68] Catalytic oxidation has been suggested as a means of freeing the exhaust gases of internal combustion engines of carbon monoxide and unburned hydrocarbon materials. J. Harger and A. Elliott (British P. 405,976, 1934; *Brit. Chem. Abs.* B, 1934, 439; *Chem. Abs.*, 1934, 28, 4869) propose conducting the exhaust through a Venturi injector, where air is admixed. The mixed gases then pass through a casing, over bauxite granules activated by impregnation with iron, copper, manganese or titanium compounds.

Heavier hydrocarbons such as paraffin wax are usually oxidized in the liquid phase at a lower temperature. Thus, Friedolsheim and Luther[72] pass liquid paraffin wax (at 100° to 220°C.) and air concurrently through two or more reaction chambers successively. These reactors are arranged one above another in such a way that a quantity of the hydrocarbon is maintained in each and reflux of the liquid is avoided while the gas bubbles through it. According to Nametkin and Zvoruikina[73] the oxidation of hydrocarbon waxes gives rise to lighter, volatile fractions, as well as the heavier acids. These lighter fractions were collected and after condensation were treated with sodium carbonate to remove acidic bodies, leaving a neutral or weakly acid oil containing the aldehyde-alcohol fraction. The latter was then washed with sodium carbonate and dilute sodium hydroxide, and afterwards with concentrated aqueous sodium acid sulphite. An oily liquid was separated from the resulting crystalline mass, and the crystals dissolved in water. The aqueous solution of the latter was extracted with ether, and the aldehydes recovered therefrom amounted to 7.7 per cent (123 grams from 1600 grams of crude aldehyde-alcohol fraction). Their boiling range indicated the presence of compounds containing five to nine carbon atoms. About 200 grams of the alcohols were recovered from the crude aldehyde-alcohol fraction. Distillation of the latter yielded cuts corresponding roughly to each of the normal alcohols from hexyl to dodecyl. These were further characterized by oxidation to the corresponding acids.

Chapter 37

Oxidation of Methane and Its Homologues

In this chapter the oxidation of gaseous and relatively low-boiling saturated aliphatic hydrocarbons is considered, not only for the preparation of alcohols, aldehydes and acids, but also from the standpoint of producing hydrogen, the oxides of carbon and unsaturated hydrocarbons. Such operations involve principally so-called quiet combustions and include as oxidizing agents, oxygen or air as well as other substances. The theories involving the mechanism of such reactions are discussed in the preceding chapter. Although several have been proposed to represent the various steps for methane and its homologues, no single explanation is without criticism.[1] Oxidation of the higher saturated hydrocarbons will be found in Chapters 42 and 43, as well as in a later section of this chapter.

OXIDATION OF METHANE

In the case of methane, as well as with its homologues, the oxidation may be made partial or complete, depending on the proportion of methane and oxygen and on the conditions of temperature and pressure, as well as catalytic materials present. For instance, Yoshikawa[2] oxidized methane under pressures of 1 to 100 atmospheres using catalysts of various degrees of effectiveness. Methanol and formaldehyde were formed as intermediate products but the amounts obtained varied in inverse proportion to the activity of the catalyst. When very reactive contact agents were employed these intermediates were absent from the final reaction mixtures. Burke and Fryling[3] treated methane with 10 per cent by volume of oxygen (50 per cent by volume of air) without the use of any catalytic material and obtained, as end products, acids and aldehydes. Reactions were carried out at 200-500°C. and under 200-1750 pounds per square inch pressure. On the other hand, when air and methane, containing only 15 per cent of the latter, were passed over a cobaltic oxide catalyst (Co_2O_3) at 500-550°C., transformation, almost completely to carbon dioxide and water, occurred. Use was made of this catalyst by Walker and Christensen,[4] in determining methane quantitatively in certain gas mixtures. They found further that nitrogen had no appreciable effect on the oxidation of methane under these conditions.

Newitt and Townend[5] conducted a series of experiments on the oxidation of methane with oxygen, in both static and dynamic systems, without the use of catalysts. In the former type, the apparatus consisted of a steel reaction cylinder of heavy construction fitted with inlet and outlet valves. In carrying out the experiments the reaction vessel was heated to the desired temperature and the hydrocarbon-oxygen mixture forced in until some predetermined pressure was attained. Temperatures were determined by means of thermocouples. The reaction could be stopped at any time merely by allowing the reactants to expand into a much larger vessel at room temperature. All products were analyzed so that a "balance" on the system could be determined. Some of the results obtained are shown in Table 178.

1000.0	Nil	63.0	1.5	69	440	7520	1	15.2

As indicated by these results, prolonged contact of the heated gases results in decomposition of the intermediate products of oxidation. The investigators observed an induction period in the early stages, during which time little chemical change took place. It was shown also that by increasing the initial pressure of the system from 48.2 to 106.4 atmospheres, the temperature of an equivalent reactivity is lowered by 30°C. After a temperature of maximum yield is reached, the latter diminishes rapidly with further increase in temperature. This together with the fact that a relatively small temperature range (20°C. at the higher pressure) separates slow from rapid reaction rates, emphasizes the importance of accurate temperature control in oxidations of this type. Experiments carried out in a circulatory system, in general, confirmed results obtained by static operation.

Paris[6] also oxidized methane with oxygen under elevated pressure and concluded that the production of methanol in appreciable quantities depended upon the fact that as the pressure is increased, the following reaction increases at the expense of other possible conversions:

$$CH_4 + \frac{1}{2}O_2 \longrightarrow CH_3OH$$

The best yields of alcohol were obtained when the oxygen concentration was low and when the temperature did not exceed 450°C. On the other hand, methanol may also be prepared under milder conditions. Thus, Cristesco[7] conducted a 3:1 mixture of methane and air through boiling water (atmospheric pressure) containing, as catalyst, lead peroxide (PbO_2) mixed with granular copper oxide. A 57 per cent yield of methanol was obtained, along with some formaldehyde and methylal. The formation of methanol was explained as taking place according to the following equation:

$$CH_4 + H_2O \longrightarrow CO + 3H_2 \longrightarrow CH_3OH + H_2$$

Extensive investigations have been carried on by Wiezevich and Frolich[8] on the direct oxidation of saturated hydrocarbons at high pressures. Laboratory and semi-commercial runs were made, both from the standpoint of producing intermediates such as alcohols and aldehydes, and also of obtaining acids as principal products. In dealing with methane, a natural gas rich in this material (2.1 per cent ethane, 6.3 per cent propane, 5 per cent nitrogen, remainder methane) was employed. In some instances, when concerned with the oxidation of mixtures of methane and ethane, this natural gas was enriched by incorporation of ethane. As oxidizing agent, 99 per cent oxygen was used, although similar results were obtained with air, provided the pressure was adjusted so as to compensate for the dilution by nitrogen. Reactions were carried on at various temperatures and the products removed by condensation and scrubbing. In Table 179 are summarized some of the results obtained using different catalysts:

Bludworth[9] oxidized a saturated gaseous hydrocarbon by a stepwise procedure. The hydrocarbons and air were introduced into a reaction chamber, the entrance and exit temperatures of the gases being 200° and 230-480°C., respectively. Further injections of air were made at various points along the tube. The final reaction products contained, among other substances, methanol, acetone and acetaldehyde. Walker[10] has suggested a stepwise oxidation of natural gas in which a series of reaction chambers is employed. The gas is mixed with a small percentage of air, this amount being sufficient however to generate enough heat (by reaction) to maintain the desired conditions of temperature within the reaction chamber. The products then pass through a heat exchanger wherein the raw incoming gas is preheated, and the condensable oxidation products (alcohols and aldehydes) duly removed. The remaining, uncondensed gas is mixed with an additional portion of air and passed to a second reaction zone where again the heat of reaction maintains the desired temperature (425 to 500°C.) of the catalyst. As catalyst, this investigator found metallic platinum on pumice satisfactory. A further suggestion made, is that the oxidation may be carried only one step, thus getting a relatively small yield of alcohols and aldehydes, the exit gases being distributed as a commercial fuel gas. This is reported advantageous in that the exit gases contain no free oxygen, although natural gas does, in some instances, contain sufficient uncombined oxygen to render it highly corrosive to pipe lines and distributing equipment. On the other hand, if natural gas is treated with an insufficiency of oxygen at considerably higher temperatures (in the range of 1000°C.), acetylene is produced.[11] Among other catalysts which have been used in the partial oxidation of methane are included, the oxides of molybdenum,[12] copper, silver or zinc oxides in the presence of aluminum phosphate,[13] metallic silver and aluminum,[14] metallic platinum, palladium, chromium, iron or vanadium,[15] and the carbide-forming metals and their oxides.[16]

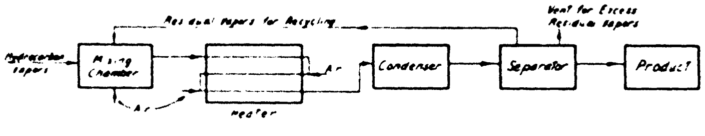

FIG. 201A.—Flow Diagram for Stepwise Oxidation of Gaseous Hydrocarbons.
(J. E. Bludworth)

Platinized silica gel[17] has been utilized in the complete oxidation of methane. Thus, a study of the effect of oxygen on mixtures of hydrogen and carbon monoxide with the gaseous saturated paraffins, using this catalyst, revealed that both hydrogen and carbon monoxide could be oxidized simultaneously at 300°C. in the presence of methane, but not when some of the higher members were present. Under these conditions methane was oxidized at about 375°C., ethane at about 250°C., propane at 150°C., and butane at 140-145°C., but the reactions were not complete even at 400°C.

If nickel catalysts and relatively high temperatures are employed, methane is converted into carbon monoxide and hydrogen, provided the correct proportion of oxygen is used. Padovani and Franchetti[18] employed temperatures of 850° to 950°C. At 900°C. less than 1 per cent of methane remained unchanged. The reaction is

$$CH_4 + \tfrac{1}{2}O_2 \longrightarrow CO + 2H_2 + 8 \text{ kg. cal.}$$

At temperatures below 1000°C. sulphur in the reacting gases, in concentrations of 0.2 to 0.25 per cent, acts as a poison for the nickel catalyst.[19]

The internal combustion engine[20] has provided means for partially oxidizing hydrocarbons. Thus, a mixture of methane and air was introduced into an engine of this type, ignited, and the size of the combustion chamber then reduced and ignition discontinued. In this way it was possible to bring about the partial conversion (i.e., the formation of methanol and formaldehyde) by means of the adiabatic compression of the mixture and at the same time to retard combustion. This scheme has also been employed by Odell[21] who used the oxides of nitrogen as catalysts, aldehydes being among the products formed.

In addition to the action of oxygen or air on methane at elevated temperatures, the effect of other oxides has also been investigated. For instance, the influence of nitrogen peroxide (NO_2) on the ignition temperature of equimolecular portions of methane and oxygen has been investigated by Norrish and Wallace.[22] The ratio of methane to oxygen was held constant and the proportion of nitrogen peroxide varied. An induction period was noted which passed through a maximum with increasing partial pressure of the nitrogen oxide. A mechanism was proposed which involved the initiation of chains by oxygen which resulted from the oxide of nitrogen present. On the other hand, Krovatzkii[23] oxidized a gas rich in methane (52-56 per cent), using oxygen, and found that the oxides of nitrogen had no catalytic effect on the reaction. The maximum yield (32 per cent) of alcohols, without the use of catalysts, was obtained at 400-500°C. At higher temperatures decomposition of the oxidation products took place with the formation of carbon monoxide, carbon dioxide and water.

Methane reacts with carbon dioxide, at 300-500°C. and under elevated pressure, to give acetic acid.[24] Alkali or alkaline earth compounds having alkaline reactions, or phosphoric acid (H_3PO_4) or a phosphate having an acid reaction may be used as catalysts.

Steam acts on methane, in the presence of catalysts, at elevated temperatures and pressures, to give aldehydes and alcohols.[25] As an example, a mixture of steam and methane (1 to 5 volumes of steam to 1 volume of methane) was conducted, under a pressure of 180-250 atmospheres, over a catalyst mass (potassium bichromate and zinc oxide) heated to 350° to 450°C. The resulting oxygenated organic compounds consisted essentially of ethanol and the higher alcohols. Aldehydes, acids and ketones were practically absent. However, when oxygen was added to the original methane-steam mixture, and a zinc chromate-cobalt oxide catalyst used, aldehydes and acids were obtained as principal products, alcohols being almost completely absent. Further, the statement has been made that steam acts on carbon monoxide, in the presence of a catalyst such as chlorine or hydrogen chloride, to give formic acid.[26]

Metallic oxides alone have been employed to oxidize methane.[27] Arneil[28] passed methane-nitrogen mixtures at various temperatures through copper oxide (CuO) impregnated with other metallic oxides. Among the latter were the oxides of cerium, chromium, iron, molybdenum and uranium. Ferric oxide (Fe_2O_3) was found to be the most effective and reduced the temperature of complete oxidation by 200°C., when present in an amount representing 4 per cent by weight of the copper oxide. The conditions were adjusted so as to effect complete oxidation, which was determined by the amount of carbon dioxide present in the final gases.

On the other hand, under proper conditions hydrogen may result from the action of cupric oxide (CuO) on methane.[29] Sarmasel natural gas (98.6 per cent methane) was oxidized by this metallic oxide at temperatures ranging between 400° and 720°C. When oxidized at temperatures below 600°C., carbon dioxide was the only gaseous product formed. Above this temperature however, both carbon monoxide and hydrogen (up to 6.5 per cent) were formed. Carbon was deposited in all instances. In variance with this is the effect of stannic oxide (SnO_2) on this natural gas. At temperatures of 700-910°C. unsaturated hydrocarbons result, very little carbon and hydrogen being formed.

Zinc oxide also serves as an oxidant for methane. Thus, Candea and Kühn[30] subjected Sarmasel natural gas (containing 98.7 per cent methane) to zinc oxide at 850° to 950°C. By varying the velocity of the gas flow over the oxide, contained in a quartz tube (20 mm. diameter), two peaks of maximum oxidation were noted, one at a gas velocity of 6 liters per hour and the other at 10.5 liters per hour. These maxima were thought to be represented, respectively, by the reactions,

$$ZnO + C \longrightarrow Zn + CO \text{ and,}$$
$$ZnO + CH_4 \longrightarrow Zn + CO + 2H_2$$

The final gases contained principally carbon monoxide and hydrogen, in a ratio of 1:5.

The oxidation of ammonia-methane mixtures to hydrocyanic acid (HCN) has been investigated by Andrussow[31] who found that for good yields the ammonia, methane and oxygen (air) must be present in the proportions represented by the equation,

$$2NH_3 + 3O_2 + 2CH_4 \longrightarrow 2HCN + 6H_2O + 229{,}800 \text{ cal.}$$

At 1000°C., 58 to 63 per cent of the ammonia is converted into hydrocyanic acid, about 8 to 12 per cent to nitrogen, and 26 to 30 per cent remains unreacted. The process is distinctly catalytic, platinum serving the purpose satisfactorily but nickel being without effect.

OXIDATION OF ETHANE

Reaction between ethane and air or oxygen appears to proceed in a manner similar to that of methane.[32] Alcohols, aldehydes and acids result from partial, and carbon dioxide and water from complete, oxidation. Ethanol, an intermediate product, may be converted, under appropriate conditions, into acetaldehyde by further oxidation, by dehydrogenation, or by these two effects occurring simultaneously. Ethane, treated with oxygen under high pressure and at moderately high temperatures, without catalysts, yields ethanol along with other substances. Newitt and Townend[33] investigated this oxidation using 88.2 volumes of ethane to 11.8 of oxygen. The tests were carried on in a closed (static) system which consisted of an electrically heated steel chamber from which the reactants could be removed at any time and cooled rapidly to lower temperatures at which the reaction stopped. They found that the reaction of ethane with oxygen under these conditions is preceded by an induction period similar to that observed in the case of methane. Ethane-oxygen mixtures react, under these circumstances, at approximately 80°C. lower than methane-oxygen mixtures of identical proportions. The results obtained from experiments at various temperatures are given in Table 180.

With respect to dehydrogenation, it has been shown that ethanol vapor passed over heated copper (200-350°C.) yields acetaldehyde.[34] This catalyst containing a small amount (1 to 5 per cent) of chromium also serves in the reaction.[35]

Partial oxidation of gaseous hydrocarbon mixtures containing ethane is described by Walker.[36] He employed oxygen at elevated temperatures and pressures, and a catalyst mass consisting of aluminum phosphate and copper oxide on pumice, and obtained alcohols and aldehydes. Mixtures of gaseous saturated hydrocarbons oxidized with oxygen containing 1 per cent or less of nitric oxide (NO) at 500-800°C., using chromium, molybdenum or vanadium as catalyst, produce formaldehyde, formic acid, acetaldehyde and other products.[37] Serbinov and Neiman,[38] in the oxidation of ethane with oxygen, observed that the conversion is accelerated several-fold by the presence of small quantities of nitrogen peroxide (NO_2), but the effect was believed not to be due to direct reaction of this oxide with ethane, but rather to a transfer of energy from nitrogen peroxide to oxygen molecules.

OXIDATION OF HIGHER PARAFFIN HYDROCARBONS

Pease and Munro[39] studied the slow oxidation of propane in an attempt to ascertain the actual steps occurring. Propane-oxygen mixtures were reacted at 400°C.

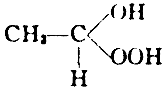
and under 1 atmosphere pressure. The gases were passed through a reaction tube heated to this temperature. The tube was 1.7 cm. in diameter and 14 cm. in length, its volume being 31 cc. Contact time was kept short so as to minimize secondary oxidation. The early appearance of propene without the equivalent of hydrogen was pointed out. As secondary products, organic peroxides, aldehydes (mainly formaldehyde) and alcohols (principally methanol) represented the main portion of the substances formed. Although some of the earlier investigators[40] failed to stress the importance of peroxides as initial products, Pease and Munro found that in some instances as high as 25 moles of peroxide were formed per 100 moles of propane used. Analytical data seemed to indicate the formula



$$CH_3-CH(OH)(OOH)$$

as representing this peroxide. On decomposing, this compound gave formaldehyde. However, by coating the reaction tube with potassium chloride, peroxides were practically eliminated without materially changing the rate of oxidation. Some of their results are listed in Table 181.

* In calculating this value the peroxide was considered as containing 2 carbon atoms and the aldehyde was taken as formaldehyde.

In the oxidation of propane with oxygen in a Pyrex flask (static method) Munro[41] observed the appearance of a fairly long induction period followed by a rapid reaction which was reported as being too rapid to permit precise measurement. This induction period, which was fairly reproducible, was measured as the time required for the pressure increase to build up to 5 per cent of its final value. However, when the walls of the flask were coated with potassium chloride, the pressure rose steadily, the induction period apparently being eliminated. Andreev,[42] in studying the oxidation of ethane with oxygen, found that metal wire such as gold, iron or copper lengthened an analogous induction period. Munro found further that with propane in excess the reaction started as low as 245°C., whereas, 306°C. was required for its initiation when oxygen predominated. On the other hand, Beatty and Edgar,[43] in oxidizing pure *n*-heptane with air, using the flow method, were unable to detect an induction period.

Wiezevich and Frolich[44] oxidized several of the lower paraffins (methane through heptanes), with air and oxygen, at high pressures. Among the catalysts used were calcium, chromel, silver, and aluminum. It was found that the higher members of the series were oxidized at lower temperatures than those required by the lower members. In dealing with a given hydrocarbon, it was learned also that lower pressures favored the formation of the lower alcohols and acids, whereas higher pressures gave more of the higher molecular weight products. This is best shown by runs made with pure *n*-butane. See Table 182.

TABLE 182.—*Effect of Pressure on Oxidation of Butane.*

	Per Cent of Oxygen

Butyl alcohols	0.6	2.5
Aldehydes	6.9	15.9
Acids	16.7	4.6
Total Useful Products	46.3	47.3

In some instances it was desired to obtain acids as main products. In such cases, the acids formed were removed (by dry lime) after each pass, the unabsorbed gases being then recirculated through the reaction chamber.[45]

It has been suggested[46] that the lower alkyl ethers, e.g., methyl or ethyl, be used as catalysts in air-oxidation of gaseous hydrocarbons such as propane. These ethers are satisfactorily employed in amounts of 1 per cent or less (on basis of hydrocarbon) and serve not only to allow oxidation to proceed at lower temperatures but also to make the velocity of reaction less susceptible to temperature variations. It is also reported[47] that alcohols, acids, aldehydes and ketones which result from the oxidation of hydrocarbons of this type (e.g., butane) may be separated from the hydrocarbon material present by extracting the mass with methanol containing water. The efficiency of the extraction is further improved by operating under superatmospheric pressures.

In the oxidation of cyclohexane with air Candea and Cristodulo[48] pointed out that this hydrocarbon favored peroxide formation more than did aromatic hydrocarbons which retarded peroxide formation and which were difficult to oxidize. In this connection may be mentioned that the oxidizability of naphthenes increases with increasing molecular weight and that their stability is further lowered by the presence of side chains.[49]

Beatty and Edgar[50] studied the oxidation of *n*-heptane as a function of temperature. The flow method was used and the reaction chamber consisted of an externally-heated Pyrex tube, 2.41 cm. in diameter and 106 cm. in length. Of this, a 65 cm. section was included in the heating zone of an electric furnace. In their experiments the pure hydrocarbon was vaporized in a current of nitrogen and later mixed with oxygen (an amount sufficient for complete combustion) so that the oxygen-nitrogen ratio was the same as that of air. The mixture was then introduced into the reaction zone, the temperatures in the various sections being measured by means of movable thermocouples. It was found that as the temperature of the gas is increased, oxidation proceeds in the following definite stages:

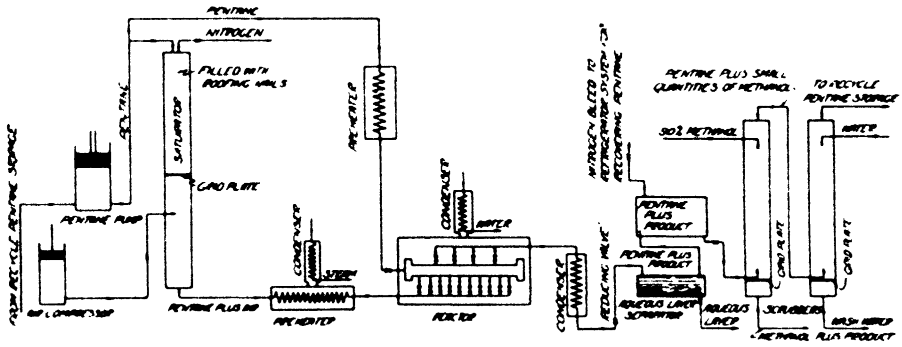
(1) At 150-250°C. a slight reaction occurs which is possibly heterogeneous.

(2) At 250-350°C. a primary reaction takes place which is terminated within the furnace. In this step 3 moles of oxygen per mole of heptane are consumed.

(3) At 350-470°C. a subsequent reaction raises the oxygen consumption to 4.7 moles. The velocity of both the primary and subsequent reactions decreases rapidly with increasing temperature.



Courtesy Industrial and Engineering Chemistry

FIG. 202.—Flow Sheet for Pentane Oxidation. (P. J. Wiezevich and P. K. Frolich)

(4) At 470-510°C. the velocity of the primary reaction continues to decrease but the subsequent reaction is accelerated and above 490°C. the final amount of oxygen used is increased.

(5) At about 510°C. inflammation occurs.

Although the complex mixture representing the reaction products was not analyzed, it was noted that some of the intermediate products exhibited extraordinary stability toward oxygen. This followed from the fact that even though a rapid increase occurred in the total amount of oxidation between 350° and 380°C., raising the amount of oxygen used to 42.7 per cent of the final value, no change whatever occurred in the oxygen consumption from 380° to 490°C. The main reaction, which began at about 250°C. and which was believed to be of the chain-mechanism type, was accompanied by visible chemiluminescence. This continued even up to the temperature of inflammation. A similar chemiluminescence was exhibited during the oxidation of 3-heptene, although the latter was attacked at somewhat higher temperatures than the corresponding paraffin. Iso-octane (2,2,4-trimethylpentane) was found to be very inert toward oxygen and when mixed with *n*-heptane had an inhibitory effect on the oxidation of the latter. This is indeed in accord with the high antiknock value of the former material when used as fuel in gasoline engines (Chapter 44).

Aldehydes averaging eight to ten carbon atoms, and proposed for use in perfumery, have been obtained by the vapor-phase air-oxidation of a cleaner's naphtha from West Texas crude oil. Oxidation was effected using nitric acid vapor as catalyst. The best yield of aldehydes (20 per cent) was secured at 444°C., together with a 25 per cent yield of acids. The aldehydes obtained were separated from other products by means of sodium bisulphite. They possessed pleasant odors when first prepared but, when exposed to the air, soon became badly rancid, due to oxidation to the corresponding acids. No alcohols were obtained when nitric acid was employed but these did appear when small amounts of tetraethyl lead, nitrobenzene, copper oleate or benzoyl peroxide were used as catalysts.[51] Böeseken and Wildschut[52] report that benzoyl peroxide may be employed as the oxidizing agent in certain reactions. These investigators conducted experiments on the oxidation of triethylmethane, using benzoyl peroxide as the source of oxygen. Contrary to expectations, it was found that a small amount of a primary alcohol was formed, indicating that a hydrogen attached to a primary carbon of one of the methyl groups had been activated, rather than the hydrogen attached to the tertiary carbon.

In the oxidation of light paraffin oils[53] at 120°C., it was found that phosphorus pentoxide, potassium hydroxide, sodium sulphate, calcium chloride, or cupric sulphate produce little effect on the reaction. It was learned however, that when means are exerted to remove water from the mixture (e.g. by suspending dehydrating agents above the liquid), the yield of acidic products is diminished.

In a rather extended study[54] of the oxidation of hydrocarbons (boiling between 175-250°C.; sp. gr. 0.77-0.85 at 15°C.), in the vapor phase by air, it was learned that at least six reactions occur simultaneously, no catalyst being found which would sufficiently increase any one of these reactions at the expense of the others. The hydrocarbon, heated to 150°C., is mixed with a limited amount of air (previously heated to 300°C.), and passed into a reaction vessel containing the catalyst. The conditions are such that only 1-1.5 per cent of carbon monoxide and dioxide are formed. The products, recovered by condensation, consist of unsaturated and aromatic hydrocarbons, aliphatic aldehydes and ketones (saturated and unsaturated), alcohols, lactones, and small quantities of acidic compounds. The various fractions obtained have been used as odorizers (sold under the name of Detektol O. Special) for odorless gases, denaturants ("Denoxol") for alcohol, and for the prevention of deposits in coal-gas lines, and as inhibitors (known as "Denoxol-Solve") for the formation of resins and gums from unsaturates.

In nitrating a cyclopentane fraction (b.p. 50-51°C.) of a Caucasian petroleum, Markownikow[55] obtained a large yield of glutaric acid, in addition to nitrocyclopentane. Nametkin[56] obtained succinic and α-methylglutaric acids by treating cyclopentane and methylcyclopentane with nitric acid. Similarly, adipic acid has been obtained from a cyclohexane fraction.

Chapter 38

Formaldehyde and Other Aldehydes

Since its discovery in the latter part of the nineteenth century as an oxidation product of methanol,[1] formaldehyde has been of ever increasing interest to chemical industry. First used as a fumigant and disinfectant, its properties of ready polymerization and a catholic willingness to condense with other substances has made it very important in the plastics industry,[2] the greatest consumer of formaldehyde at present. Although formaldehyde has a sharply irritant odor, the higher aldehydes differ in this property and some are used in the manufacture of perfumes and as solvents.[3]

Formaldehyde is generally available as the 40 per cent aqueous solution (formalin), as the solid polymer, paraformaldehyde, which deposits from the water solution, and also as the compound formed with ammonia, hexamethylenetetramine. The aldehyde is readily regenerated by heating the latter substance with acid. Another solid polymer, polyoxymethylene, is formed directly by polymerization of the liquid or gaseous monomer, sometimes with explosive violence.[4] The gaseous monomer condenses to a liquid at —19.2°C. which freezes at —118°C., according to Spence and Wild,[5] but is stable only at temperatures near that of liquid air, due to the strong tendency to form polyoxymethylene. Maintained in a solid carbon dioxide-ether bath, polymerization still proceeds to such an extent that interlocking fine crystals of the polymer convert the aldehyde to a gelatinous mass. So insoluble is this polymer in the liquid monomer, however, that no effect was discernible on the vapor pressure curve of the latter. Spence and Wild[6] believed that this polymerization of liquid formaldehyde to polyoxymethylene took place progressively from solid nuclei or solid surfaces. In an effort to test the belief, gaseous formaldehyde (obtained by heating paraformaldehyde) was specially treated to free it of any entrained solid matter. The liquid prepared by condensing this gas in a liquid air-cooled trap proved to be distinctly more stable than liquid formaldehyde prepared from gas not thus freed of solids. However, even this more stable liquid polymerized slowly from the solid surfaces of the containing vessel.

OXIDATION OF ALCOHOLS

Formaldehyde is an oxidation product of methanol, and this method of production has maintained its preeminence to the present time since the process is simple, the products readily purified, and the raw materials not costly. Oxidation of the corresponding primary alcohol is a general method for preparing formaldehyde or its higher homologues. The aldehydes can also be prepared by dehydrogenation reactions, without oxidation. Smolenski and Kowalewski[7] reported that dehydrogenation was promoted by a copper catalyst. Thus they obtained acetaldehyde by the dehydrogenation of ethyl alcohol heated in the presence of copper. Young[8] found that the copper catalyst was further activated by the addition of 1 to 5 per cent of chromium. It was prepared by impregnating a porous artificial filter stone support with mixed cupric and chromic nitrates, followed by reduction in a stream of ethyl alcohol vapor. The catalyst was then used at a temperature of 225 to 350°C., the ethyl alcohol vapors being passed over it under 0.5 to 5 atmospheres pressure. Similar dehydrogenation reactions may be carried out in the liquid phase. Thus, according to Brus,[9] anhydrous zinc sulphate reacts with ethyl alcohol, first converting it to acetaldehyde and then condensing the latter product (with loss of water) to crotonaldehyde. With *n*-propyl alcohol the action is similar, although isopropyl alcohol is dehydrogenated to acetone. The latter substance is condensed to mesityl oxide and phorone. That acetone was a primary product of dehydrogenation was confirmed by treating some of this ketone with the anhydrous sulphate and testing for mesityl oxide and phorone. Butyl alcohol is similarly converted to butyraldehyde, which in turn furnishes an iso-octenyl aldehyde. When polyhydric alcohols such as glycerol are treated in this manner, dehydration takes place, leading, in the case of glycerol, to acrolein.

However, the usual procedure consists of a catalytic oxidation by air or oxygen. The importance of the reaction has led to considerable investigation of possible catalysts, and though copper, silver, or a mixed copper-silver mass is generally used,[10] various investigators have proposed oxides of molybdenum, vanadium, iron, lanthanum, thorium, neodymium, zinc or tin,[11] or certain of these substances as well as cerium, aluminum or chromium used in conjunction with electrolytic silver crystals.[12] Nevertheless, Dolgov and Bocharova,[13] after detailed experiments with synthetic methanol and air, reported that the metallic catalysts other than silver and copper were of little use. Their findings indicate that most metal oxides are not satisfactory but that a catalyst consisting of copper discs placed close together (within the reaction zone) gave a yield of 42 per cent of formaldehyde. Copper oxide with an activator such as thorium or uranium furnished yields of 21 to 42 per cent. On the other hand, Ghosh and Baksi[14] reported that cerium and thorium were advantageous promoters for copper catalyst. Ivannikov and Zherko,[15] however, working on this same problem, tested these metals and found the results disappointing. They believed that this cerium-promoted copper catalyst favored the production of methyl formate rather than formaldehyde. They also suggest that the results reported by Ghosh and Baksi may have been misleading due to the

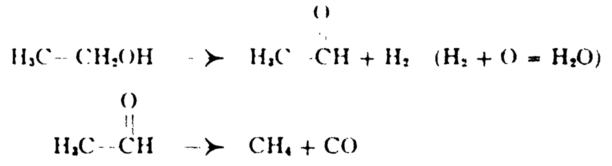
method of analysis employed, i.e., testing by gas analysis, since methyl formate and formaldehyde possess identical empirical formulas.

Gurevich and Chirvinskaya[16] found that copper gauze was the optimum catalyst, the most desirable temperature being 360°C., when the gas was composed of methanol with 52 to 57 per cent of the theoretical amount of oxygen. Under these conditions, yields of 92 to 93 per cent of formaldehyde were secured. Silver on pumice gave a 90 per cent yield, and when this metal was deposited on copper gauze, 92 per cent of the theoretical quantity was obtained. If the oxygen content of the reacting gases was increased, the yield fell rapidly. Simultaneous oxidation to carbon dioxide and formaldehyde occurred, the latter then breaking down to carbon monoxide and hydrogen. Bond and Smith[17] prepared a silver catalyst for the oxidation of methanol by forming a compacted mass of silver oxide without inert diluent and subsequently reducing this mass to silver. This was further activated by incorporation of such other metals as cerium, thorium, chromium, molybdenum, vanadium, tungsten or zinc.

In oxidizing the higher primary alcohols to the corresponding aldehydes, there is some tendency to completely oxidize off the carbinol groups with resultant degradation to the next lower aliphatic compound. Thus, Flanzy[18] reported a study of ethyl alcohol-oxidation catalyzed by copper oxide, which indicated that considerable quantities of formaldehyde were formed at 300°C. He proposed a mechanism for this reaction as follows:

$$H_3C\ \ CH_2OH \xrightarrow{\frac{1}{2}O_2} H_2C{=}CHOH + H_2O \rightleftharpoons H_2C{=} + {=}CHOH$$
$$=CHOH \longrightarrow HCHO$$

In an investigation of the oxidation of ethyl alcohol to acetaldehyde, using copper gauze as catalyst, Nikolskii[19] concluded that the process was one of dehydrogenation with subsequent oxidation of the hydrogen split off. He believed carbon monoxide to be the result of decomposition of the acetaldehyde formed, as follows:



$$H_3C{-}CH_2OH \longrightarrow H_3C{-}\overset{\overset{\displaystyle O}{\|}}{C}H + H_2 \quad (H_2 + O = H_2O)$$
$$H_3C{-}\overset{\overset{\displaystyle O}{\|}}{C}H \longrightarrow CH_4 + CO$$

His work indicated that the reactions were due to the high temperature (600 to 700°C.) of the contact mass and the low concentration of oxygen employed. By increasing the size of the reaction chamber and reducing the catalyst temperature to 400°C., it was possible to raise the oxygen content of the entering gases to 55 or 60 per cent and to use a heavier gauge of copper gauze. This eliminated a second source of trouble, the fusion of the fine copper mesh to a sintered mass due to the heat of oxidation of hydrogen on the surface of the catalyst.

Patterson and Day[20] oxidized ethyl alcohol (with air) to acetaldehyde (using a silver catalyst) at pressures ranging from 1 to 50 atmospheres. The yield and the yield efficiency (ratio of alcohol converted to aldehyde to the total alcohol oxidized) both decreased as the pressure mounted. The data in Table 183 indicate also that considerable decomposition of intermediate products to hydrocarbon and hydrogen took place:

Butyl alcohol can be oxidized with either air or carbon dioxide, according to Rubinshtein and his associates.[21] Catalysts of chromic, manganic, ferric and vanadic oxides, precipitated silver, copper and silver-copper, and various combinations of these were tested. With air as an oxidant, a catalyst of silver (precipitated from a silver-ammonia complex by formaldehyde) mixed with 4 per cent of a copper-silver mixture was most successful, giving a yield of 68 per cent butyraldehyde with 7 per cent butyric acid at 350° to 360°C. Although less effective, ferric and vanadic oxides catalyzed the reaction at higher temperatures (400° to 550°C.), but the other metal oxides tested were useless. Vanadic oxide was reported satisfactory, however, when using carbon dioxide as the oxidizing agent, at a temperature of 550°C.

CATALYTIC OXIDATION OF HYDROCARBONS TO ALDEHYDES

Due to the large quantities of hydrocarbons available at very low cost in natural gases, interest has been aroused in catalytic oxidation producing aldehydes directly from them. Even without catalysts, the reaction takes place to a certain extent. Frear[22] investigated this action using a silica tube 1.37 cm. in diameter, the reaction being carried out at atmospheric pressure or lower, with temperatures close to 600°C. With a methane-oxygen ratio (presumably by volume) of 77 to 21 at atmospheric pressure, the formaldehyde yield increased with increasing contact time until a maximum was reached at 54 seconds. Under these conditions a 0.23 per cent yield of the aldehyde was obtained, together with 10.9 per cent carbon dioxide and 0.14 per cent of carbon monoxide. Contact times greater than 54 seconds decreased the yield and, at 103 seconds, but 0.035 per cent of formaldehyde was formed, while 13.2 per cent of carbon dioxide was produced. From these data, Frear concluded that in an unpacked silica tube the reaction is of the chain type of the 3.45 order[23] under pressures between 450 and 575 mm., the order increasing rapidly with the pressure. In a packed tube the reaction is of the first order and, at pressures below 300 mm., proceeds more rapidly than the chain mechanism.

[23] This fractional order number indicates that calculations based on experimentally determined re-

In industrial work, however, catalysts are almost invariably employed. In a process described by James,[24] oxygen and methane are circulated through a reaction chamber in which the "blue oxides" of molybdenum are used as catalysts. The gases then pass to a chamber in which the desired oxidation product (formaldehyde) is separated out. The unreacted gases are recirculated with the addition of fresh oxygen and methane to replace that converted. Tikhomirova and Monakhova[25] used a mixture of cracking gas and air, with a catalyst of vanadic oxide precipitated on kaolin. The reaction was carried out at 280° to 340°C., yields of from 5 to 11 per cent formaldehyde, 2 to 3.5 per cent formic acid, and 6 to 7 per cent of acetic acid being obtained. Tikhomirova[26] found that copper gauze decreased rather than increased the proportion of formaldehyde when used in conjunction with the vanadic oxide catalyst. The optimum degree of oxidation was obtained by 8 to 10 recyclings of the gaseous mixture.

Solid catalysts are not always used alone but sometimes are aided by gaseous catalysts, particularly the oxides of nitrogen.[27] As an example, the methane-oxygen mixture may have added to it less than 1 per cent of nitric oxide and the gases then passed over solid catalysts at temperatures between 600 and 700°C. The reaction may be carried out in the presence of zinc or zirconium and oxides or carbonates of such metals as aluminum, chromium, vanadium, molybdenum, tungsten, manganese, nickel or cobalt.[28]

Sheely and King[29] oxidized a cleaner's naphtha (from West Texas crude oil) in the vapor phase, using nitric acid vapor as catalyst. The best yield of aldehydes (20 per cent) containing 8 to 10 carbon atoms, along with some acids, was obtained at 444°C. The aldehydes possessed pleasant odors and were suggested for use in perfumery.

Electro-Catalytic Production of Aldehydes

Since, as already noted, oxides of nitrogen are sometimes used as catalysts in the oxidation of methane-oxygen mixtures, a number of methods have been proposed which combine the manufacture of the nitrogen oxides with their utilization in this process. Thus, Harter[30] suggested that air be blown through an electric arc causing the formation of mixed nitrogen oxides which are, however, unstable at the lower temperatures outside the arc. Methane or other hydrocarbon is blown into the apparatus to be mixed with the stream of unstable and decomposing nitrogen oxides escaping from the immediate region of the arc. The decomposition of the oxides releases oxygen in a highly activated form so that the hydrocarbon is oxidized at comparatively low temperatures, e.g., 100 to 500°C. Under these

---

action velocity constants showed the series of reactions proceeded at a rate less than that of a third order reaction, though greater than that of a fourth order reaction. For a discussion of reaction orders, see Chapter 20.

conditions the partial oxidation products are relatively stable. "Bleaching earths," silica gel, or metallic catalysts may be used as additional catalysts to direct the oxidation to the formation of formaldehyde. A method described by Nashan[31] uses an undamped, visible discharge of high-tension, high-frequency alternating current as the activating agent. In this case the nitrogen oxides produced are somewhat more stable and react with the hydrocarbon (methane, for instance) to produce partial oxidation products, but also a quantity of the nitrogen is sufficiently activated to further react with some of the formaldehyde produced. The products of this process include not only formaldehyde, but also hexamethylenetetramine, which can be recovered by solvent extraction and recrystallization. Nashan[32] also reported that oxygen may be used as the oxidizing agent in such a high-frequency, high-tension field if less than atmospheric pressure is applied. If methane is used as the hydrocarbon, a good yield of formaldehyde is obtained. Fujimoto[33] found that a similar mixture produced dihydroxydimethylperoxide ($HOCH_2OOCH_2OH$) when treated with the silent electric discharge. This compound is fairly stable, but breaks down on heating with or without a catalyst (platinum black or zinc may be used) to yield formaldehyde, formic acid, acetaldehyde and methyl alcohol.

FIG. 203.—Oxidation of Hydrocarbon Gases with Nitrogen Oxides Formed in Electric Arc. (H. Harter)

Not only can the electric discharge bring about combination of hydrocarbons with oxygen, but carbon dioxide may be used as the oxidizing agent in the discharge. Finlayson and Plant[34] reported a method for the production of acetaldehyde and formaldehyde based on the oxidation of methane by means of carbon dioxide. The gaseous mixture was passed through an electric discharge supplied with alternating current at a frequency of about 1000 cycles. Other investigators have shown that by varying the proportions of methane to carbon dioxide, the products are accordingly varied. Thus, if an excess of methane is present, the reaction tends to produce acetaldehyde,[35] but if the carbon dioxide concentration is equal to or greater than the methane concentration, the product is principally formaldehyde.[36]

Fester and Schivazappa[37] investigated the electrolytic reduction of carbon monoxide and concluded from their results that only traces of formaldehyde are formed in this manner, since this lower oxide of carbon is not a true unsaturated compound. However, they believed that a combination of catalytic and electrolytic reduction in solution should give determinable amounts of the aldehyde, and this conclusion was verified by experiments. Very small quantities of formic acid and methyl alcohol were formed simultaneously.

DECOMPOSITION OF ALDEHYDES

The high temperatures used in the catalytic oxidations of the gaseous hydrocarbons to aldehydes lead to considerable decomposition of the desired products. Spence[38] finds that formaldehyde, for instance, reacts rapidly with oxygen in a Pyrex tube at 317°C. In an unpacked tube, the products are largely carbon monoxide and water, but in a tube packed with powdered glass, carbon dioxide and water are produced. In addition to loss of product through such oxidation as this, purely thermal decomposition is a considerable factor. The mechanism of this decomposition has been studied in a number of ways. Patat and Sachsse[39] took advantage of the fact that atomic hydrogen is a catalyst for the conversion of parahydrogen to orthohydrogen in tracing the reaction.[40] In this way it was possible to show that no more than very minute quantities of free hydrogen radicals could be present. Tests were made using formaldehyde and parahydrogen heated together at a temperature of 823°C. A total pressure of 625 mm. was used, 600 mm. due to parahydrogen and 25 mm. pressure of formaldehyde. No decrease in the concentration of parahydrogen was detected. Work with formic acid (20 mm. partial pressure) and parahydrogen (760 mm.) heated together at 300 to 440°C. gave similar negative results. It was concluded from the data that the decomposition of such methyl compounds proceeds through saturated substances. The same investigators also report that the free-radical, or chain mechanism, cannot be applicable in these decompositions. The parahydrogen results indicate so low a concentration of free hydrogen atoms that an improbably high heat of activation (29,000 cal.) must be postulated to account for the acetaldehyde decomposition on the basis of a chain reaction. Winkler and Hinshelwood[41] arrived at a similar conclusion from investigations of the effect of surface-volume ratios on reaction speed. Results obtained from operations at a temperature of 562°C. and an initial pressure of 240 mm. gave no evidence that the decomposition of acetaldehyde was heterogeneous or depended on a chain reaction. Staveley and Hinshelwood[42] have shown that sufficient nitric oxide (NO) may accelerate the decomposition of acetaldehyde, although smaller amounts do not have this effect; neither do small percentages inhibit the decomposition. On the other hand, partial pressures of nitric oxide in the range near 2 mm. do act to inhibit the decomposition of propionaldehyde. However, increasing the amount of nitric oxide present diminishes this effect, until a positive catalytic effect is finally exerted when large proportions of the nitrogen compound are present. The investigators believe that the decomposition of the latter aldehyde involves a short (2 unit) chain reaction, although the decomposition of acetaldehyde involves no chain mechanism.

[40] The parahydrogen molecule differs from the orthohydrogen molecule in that the proton spin of the two hydrogen atoms forming the ortho molecule is in the same direction; in the para molecule the two protons spin in opposing directions. The two forms of the molecule differ in various physical properties, such as specific heat and thermal conductivity. Normal hydrogen gas contains both forms in ratio of 1 parahydrogen to 3 orthohydrogen molecules, according to K. F. Bonhoeffer and P. Harteck (*Naturwissenschaften*, 1929, 17, 182; *Chem. Abs.*, 1929, **23**, 2614.). Practically pure parahydrogen can be prepared by adsorption on activated carbon at liquid hydrogen temperatures. So prepared, the para molecules are sufficiently stable to remain practically unchanged for a week at room temperature. Hydrogen atoms, platinum black, and certain other substances catalyze the conversion to the 1 to 3 equilibrium mixture nearly instantaneously.

A number of substances frequently present as intermediates in the production of aldehydes from hydrocarbons by oxidation are catalysts for the decomposition of aldehydes. Letort[43] reports that traces of oxygen act in this manner at temperatures in the range of 477°C. Fletcher[44] found that ethylene oxide in small quantities induces a decomposition of acetaldehyde below 500°C. The conversion is proportional to the square root of the ethylene oxide pressure and to slightly less than the first power of the acetaldehyde pressure. Decomposition is retarded by the presence of diluent gases (e.g., helium), but the course of the reaction is unchanged. According to Verhoek[45] nitrous oxide also exerts a catalytic effect on the decomposition. In this case, there appears to be a reaction between the aldehyde and the nitrogen oxide to produce a substance which is the active catalyst or the initiator of a chain reaction. In a clean silica bulb, the catalyzed reaction is of the first order with respect to acetaldehyde. Letort[46] finds that carbon monoxide and methane exert a retarding effect on the decomposition of acetaldehyde, and although there appears to be both an activating and deactivating effect, the latter greatly predominates. The presence and accumulation of these products retard the decomposition reaction in such a way that, though it starts as a mechanism of the 1.5 order, during the course of the action, the order number rises to 1.8.

RECOVERY AND REMOVAL OF ALDEHYDES

The direct concentration of formaldehyde solutions is difficult due to the formation of azeotropic mixtures and the tendency to precipitate the polymer, paraformaldehyde.[47] Korzhev and Rossinskaya[48] report that formaldehyde forms an azeotropic mixture with water in 11 to 12 per cent aqueous solutions. At concentrations above 12 per cent, the proportion of formaldehyde in the vapor is less than that in the initial solution, and the aldehyde accumulates in the solution. If there is less than 8 or 9 per cent of formaldehyde in the solution, distillation yields a product richer in the aldehyde. These investigators postulate an equilibrium between formalin hydrate [$CH_2(OH)_2$], paraformaldehyde [$(CH_2O)_n$] and formaldehyde. When distillation is carried out under reduced pressure, the concentration of formaldehyde in the vapor decreases while that in the residue increases. Korzhev, Frolova and Rossinskaya[49] found that if crude dilute formaldehyde is made neutral with calcium hydroxide and the water distilled off at 30 mm. pressure (conditions under which the aldehyde does not go over), the distillation can be completed at atmospheric pressure to give a 37 per cent solution. From a 13 per cent formaldehyde solution a concentrated distillate may be obtained by adding calcium chloride to make a 33 per cent brine, and distilling at atmospheric pressure. Hasche[50] reports a similar distillation, adding that substances capable of raising the boiling point of the solution sufficiently to decompose the polymers of formaldehyde will permit distillation of concentrated solutions. He suggests the chlorides of magnesium and zinc as well as that of calcium.

[47] However, W. S. Hinegardner (U. S. P. 2,002,243, May 21, 1935, to E. I. du Pont de Nemours & Co.; *Chem. Abs.*, 1935, **29**, 4381) reports that water solutions of formaldehyde are made more stable by the addition of 5 to 10 per cent of hydrogen sulphide. A reversible reaction takes place between the aldehyde and the sulphide, preventing precipitation of polymers. The sulphur compound is most stable at lower (0 to 5°C.) temperatures when the aldehyde is least stable

REACTIONS OF ALDEHYDES

The carbonyl group of the aldehydes is typified by its high reactivity,[51] and although a detailed discussion of the aldehyde reactions is beyond the scope of the present text, some mention of the more important reactions must be made. According to Richter[51a], the high reactivity of the aldehydes places them among the most important substances for purposes of synthesis. An aldehyde is readily converted to the corresponding carboxylic acid, on oxidation, and consequently serves as a powerful reducing agent. Thus if acetaldehyde and air (an excess of oxygen being avoided) are passed over an oxidation catalyst at 40 to 70°C. under 50 to 100 pounds per square inch pressure, the corresponding acid, acetic acid, is formed. If dry gases are used, and a dehydrating agent is present during the reaction, acetic anhydride is also obtained. It is reported that an acetate, butyrate or propionate of manganese serves as a catalyst in this reaction, and may be mixed with an activator such as copper, nickel or cobalt acetates. In producing the anhydride, the aldehyde is oxidized to an extent of about 70 per cent, then the gases are cooled quickly to 20°C.[52] If an aldehyde is warmed with a dilute ammoniacal silver solution, silver is precipitated in the form of a mirror on the walls of the containing vessel. In the presence of nascent hydrogen, however, the aldehydes readily reduce to the corresponding primary alcohol. With acid anhydrides, the aldehydes react to form esters of the hydrated form of the aldehyde, the α, α-glycol:

$$R-CHO + (R'CO)_2O \longrightarrow R-CH(O-COR')_2$$

The aldehydes react with ammonia to form aldehyde-ammonias which are readily soluble in water but rather unstable, breaking down in the presence of acids to yield the original components. Pyridine bases are produced when these aldehyde-ammonias are heated. When an aldehyde is warmed with an aqueous solution of hydroxylamine, aldoximes of well defined properties are formed which are frequently helpful in identifying a particular aldehyde. With acetaldehyde, acetoxime is formed:

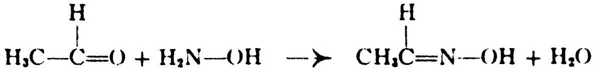
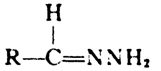
[52] British P. 446,259, 1936, to Shawinigan Chemicals Ltd.; *Chem. Abs.*, 1936, **30**, 6765; *Brit. Chem. Abs.* **B**, 1936, 920.



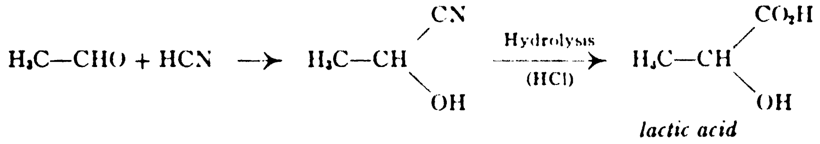
$$H_3C-\overset{\overset{H}{|}}{C}=O + H_2N-OH \longrightarrow CH_3\overset{\overset{H}{|}}{C}=N-OH + H_2O$$

Hydrazine reacts similarly with aldehydes to produce compounds of the type



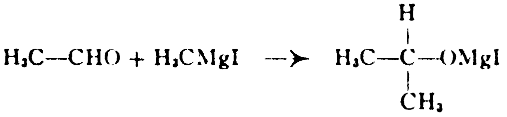
$$R-\overset{\overset{H}{|}}{C}=NNH_2$$

With hydrogen cyanide, a reaction takes place yielding cyanohydrins, nitriles of α-hydroxyacids. These cyanohydrins can be converted to the acids by means of hydrochloric acid:



With ammonium cyanide, aldehydes react to form the nitriles of α-amino acids, which, when treated with hydrochloric acid, yield the amino acids.

The aldehydes are also able to react with Grignard reagents:



$$H_3C-CHO + H_3CMgI \longrightarrow H_3C-\underset{\underset{CH_3}{|}}{\overset{\overset{H}{|}}{C}}-OMgI$$

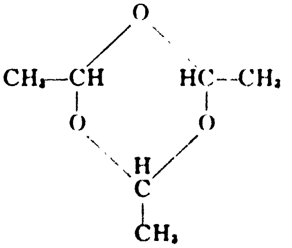
The reaction product yields secondary alcohols on hydrolysis with water or acids.

Under suitable conditions (e.g., in the presence of zinc chloride) aldehydes undergo a type of condensation whereby two or more aldehyde molecules become linked:

$$H_3C-CHO + H_3C-CHO \longrightarrow H_3C-CH(OH)CH_2CHO$$

A similar reaction can take place between two different aldehydes.[53]

Aldehydes polymerize in the presence of alkalies to form aldehyde-resins, a reaction characteristic of all the aliphatic aldehydes save formaldehyde. With acids, however, the polymerization is of a different nature, leading to the formation of paraldehyde, in the case of acetaldehyde, with the strong evolution of heat. The vapor pressure and density data indicate that the composition corresponds to $(C_2H_4O)_3$. Paraldehyde does not show the reactions characteristic of the carbonyl group but probably has the structure,



with linkage taking place through the oxygen atoms.

---

[53] V. von Richter, "Organic Chemistry," English Edition (Third) by E. N. Allott, Kegan Paul, Trench, Trubner & Co., London, 1934.

The study of the aldehydes has been made more difficult in some cases by the readiness with which these substances polymerize forming hydrates and condensation products. Reiche and Meister[54] found that ether solutions of formaldehyde, prepared by shaking ether with 40 per cent aqueous solutions of the aldehyde, did not contain free HCHO, but instead, the hydrate $CH_2(OH)_2$. They reported that solutions prepared in this manner are stable for weeks, deposit no polymers on long standing, and have only a faint odor. On the other hand, a solution prepared by passing gaseous formaldehyde into ether has a powerful, extremely penetrating odor, and continuously precipitates polymeric formaldehyde. This polymerization takes place so rapidly that the concentration of the monomer is reduced to 50 per cent of its original value in even a few hours. An ether solution of anhydrous formaldehyde (prepared from dry ether and gaseous aldehyde) reacts with hydrogen peroxide to produce hydroxy-methyl-hydroperoxide ($HO\text{-}CH_2\text{-}OOH$) as a relatively stable oil which is not sensitive to friction but which explodes violently when heated in a flame. With alkali the peroxide compound yields 97 per cent formic acid and evolves hydrogen and oxygen. With ferrous sulphate, a reaction takes place yielding 50 per cent formic acid and 50 per cent formaldehyde. Briner and Lardon[55] report a study of the ozonization of the lower aliphatic aldehydes in solution in water, carbon tetrachloride and hexane. Ozonization of acetaldehyde, propionaldehyde or butyraldehyde in each of the solvents showed a marked increase in the ratio of moles of oxygen fixed to moles of ozone consumed as the series was ascended. The increase is more marked with aldehydes of higher molecular weight. Very little autoxidation of the aldehydes was found to take place in water solution, but the solvent involved had pronounced effect on the way in which the oxygen of ozone was fixed in the molecule. Thus, in carbon tetrachloride, most of the combined oxygen went to form the corresponding acid from the aldehyde. In the cyclohexane solutions, large proportions of peracid were formed. Formaldehyde differed from the higher aldehydes in that it was only slightly attacked by ozone, either in the solvents or in the gaseous state.

Krauskopf and Rollefson[56] studied the photochemical reaction between chlorine and gaseous formaldehyde and found that a small amount of formyl chloride can be prepared. The two gases were reacted in a quartz bulb (and in later tests in a tube spiraled about a 300 watt tungsten lamp) and then led to a liquid air trap where the condensible reaction products (largely hydrogen chloride) were frozen out. Carbon monoxide was pumped off from the trap. Fractional distillation and extractions of the condensed material concentrated the formyl chloride produced. This substance is highly unstable and breaks down very rapidly at room temperature to yield carbon monoxide and hydrogen chloride, making it impossible to get a purified sample of the material. It was found that in water the reaction likewise produced the monoxide and hydrochloric acid, with no tendency to hydrolyze to formic acid. It was possible, however, to prepare the derivative *assym*-formo-*m*-xylidide, melting at 114 to 115°C. Although formyl chloride is stable only at the temperature of liquid air, formyl fluoride prepared by Nesmejanow and Kahn[57] (by reacting formic acid and potassium fluoride in benzyl chloride or trichlorophenylmethane solution) was fairly stable at room temperature, decomposing only after 4 hours or so. The fluoride, moreover, does hydrolyze to formic acid.

Hexamethylenetetramine, $(CH_2)_6N_4$, obtained by the reaction of formaldehyde and ammonia, readily regenerates formaldehyde on treatment with an acid. The. structure of this compound is not definitely known, and Dominikiewicz[58] proposes a structure basing his conclusions largely on the results of various benzoylation reactions. With acetic anhydride in cold ethyl ether, hexamethylenetetramine yields:

---

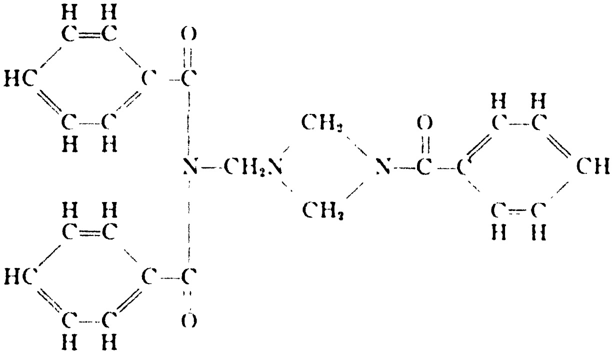
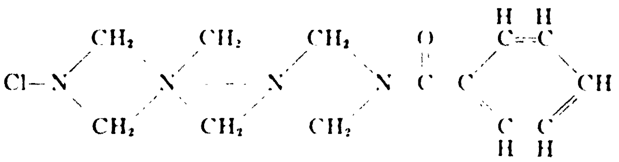
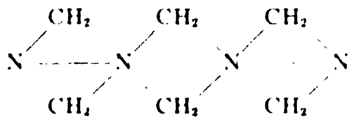
An analogous di-benzoyl derivative cannot be prepared, due to the further benzoylation to trimethylenetribenzoyltriamine:



A further benzoylation product of similar structure containing four benzoyl groups, dimethylene-N,N′-bismethylenedibenzoylaminediamine, can also be prepared. Benzoylation of hexamethylenetetramine in chloroform in the presence of pyridine gives chloro-benzoylhexamethylenetetramine:



On the basis of these and certain other experiments, the formula



is attributed to hexamethylenetetramine.[59]

Aldehydes also react fairly readily with aliphatic nitro compounds to give nitro-alcohols and glycols. This type of reaction is discussed more fully in another section, however.[60]

[59] The aldehydes undergo many reactions resulting in the formation of useful resins, but this is beyond the scope of the present text. For discussion of this material see Carleton Ellis, "The Chemistry of Synthetic Resins," Reinhold Publishing Corp., New York, 1935.

[60] See Chapter 47.

UTILIZATIONS OF THE ALDEHYDES

As has been noted, various higher oxidation products such as carboxylic acids can be produced from aldehydes. Wiesler[61] oxidized acetaldehyde in the liquid phase (at 55° to 80°C.) to acetic acid. The oxidation of higher iso-aldehydes to produce the corresponding iso-acids has been described by Groll and Tamele.[62] Moskovits[63] carried out the oxidation of aldehydes in the presence of an alcohol and obtained 91 per cent yields of the corresponding esters. Acetic acid can be produced from formaldehyde at 300-400°C., according to Green and Spondon.[64] In this case 100 atmosphere pressure is used to bring about the condensation.

The aldehydes will polymerize or condense with themselves readily. Hoffer[65] reports forming unsaturated high molecular weight aldehydes from lower saturated aldehydes by using a secondary organic base or its salt as catalyst. Various formals (and mixed formals) can be prepared by direct reaction of different alcohols with formaldehyde.[66] The higher formals, such as those formed from dodecyl or cetyl alcohol, produce readily emulsified materials useful in treating textiles.[67]

The lower aldehydes can be made to yield those of greater molecular weight by using the aldol condensation as an intermediate step. According to Kagan and his associates[68] acetaldehyde in the presence of 2 per cent alkali solution condenses to yield 97 per cent of the theoretical quantity of crotonaldehyde. This latter product was hydrogenated in the vapor phase (using a copper catalyst) to obtain butyraldehyde and butanol. Reduction of an aldehyde by means of aluminum isopropoxide, $[(CH_3)_2CH\text{-}O\text{-}]_3Al$, produces the corresponding alcohol, Young, Hartung and Crossley report.[69] They have obtained butanol from butyraldehyde by this means. Reduction of the condensation product of the reaction of aldehydes will yield alcohols of high molecular weight. Thus, butyraldehyde and heptadecaldehyde undergo an aldol-like condensation in the presence of secondary amines such as diethylamine. The product of this condensation can be hydrogenated (with catalysts such as nickel) to produce higher mono- and polyhydroxy alcohols (e.g., octyl alcohol).[70] The condensation of lower polyhydroxy alcohols (such as ethylene glycol) with aldehydes yields distillable diethers:

Dreyfus[71] reports that this reaction is catalyzed by the presence of pyrosulphates or pyrophosphates.

As has been pointed out, one important reaction of formaldehyde in industry is that of its condensation with various other substances (e.g., phenols, urea, casein) in making synthetic plastics.[72]

The separation of the complex mixture of products resulting from oxidation of petroleum, representing practically all stages of oxidation, presents considerable difficulties. Ellis[73] suggested a means of direct utilization of these products which does not require their separation. Inasmuch as the greatest demand for aldehydic materials is in the plastics industry, the petroleum aldehydes present can be directly separated by their condensation to a synthetic resin. One hundred and fifty parts of a mixture of oxidation products containing 27 per cent formaldehyde, 3 per cent acetaldehyde and considerable methanol along with a small proportion of ethanol was reacted with 60 parts of urea. A material was produced which was white, plaster-like and practically odorless. Resins can also be obtained by condensations of the aldehydes with phenols, thiourea or ammonium thiocyanate. During the oxidation of petroleum to produce aldehydes, there is simultaneously formed a gummy, semi-resinous mass of higher molecular weight oxidation products. Ellis has shown that this tarry complex possesses phenolic properties and suggests that these substances be condensed with the simultaneously produced petroleum aldehydes. The material resulting is a hard, infusible, insoluble resin which may be employed in molding or coating compositions.

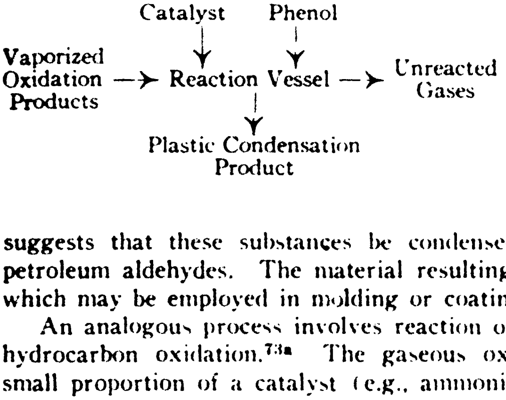

FIG. 203A. Flow Chart for Reaction of Phenols with Aldehydic Hydrocarbon Oxidation Products. (O. R. Sweeney, F. C. Vilbrandt, H. H. Beeson and H. A. Montgomery)

An analogous process involves reaction of phenols with aldehydes obtained by hydrocarbon oxidation.[73a] The gaseous oxidation products are mixed with a small proportion of a catalyst (e.g., ammonia) and contacted with phenol, either molten, vaporized or in solution, reaction taking place at 50-150°C. In this manner bodies of an aldehydic character are removed as a plastic condensation product, leaving as unreacted material vapors consisting essentially of alcohols and ketones.

Uses have been developed for the aldehydes or their polymers without combination with other substances. There has been some interest in the possibilities inherent in the polymerization of the higher aldehydes to synthetic resins.[74]

According to van der Wal[75] aldehydes materially improve the characteristics of pickling solutions used in cleaning metals. Aldehyde polymers of various types are employed, as well as hexamethylenetetramine.[76] The ability of formaldehyde to precipitate proteins is important in making waterproof glues, coating materials and cements.[77] By treating bone or skin glue with formaldehyde and adding the product to cement, the tightness is considerably increased.[78] If phosphorus-containing proteins are treated with formaldehyde, a product capable of stabilizing bituminous emulsions is formed.[79] An emulsifying agent giving soap-like reactions, capable of splitting fats, and forming solutions which foam readily on shaking can be prepared by condensing formaldehyde with a strongly basic non-aromatic amine (such as diethyl amine) and a substituted phenol such as α,α,γ,γ-tetramethylbutylphenol.[80]

Chapter 39

Oxidation of Unsaturated Hydrocarbons

FORMATION OF UNSATURATED HYDROCARBONS

In general, the olefins react more readily with oxygen than do the corresponding saturated hydrocarbons. However, oxidation does not necessarily split the molecule at the double bond but may proceed so as to give intermediate products such as epoxides,  $R{-}\overset{\diagup O \diagdown}{CH{-}CH}{-}R'$, peroxides,  $R{-}\overset{O{-}O}{\overset{|\quad\;|}{CH{-}CH}}{-}R'$, glycols or acids. (Note: R and R′ may be hydrocarbon radicals or hydrogen atoms, etc.)

The major source of olefinic compounds is the cracking of petroleum hydrocarbons, and this source alone supplies the demand almost completely. They can be produced, however, by partial oxidation of the corresponding saturated hydrocarbons. These oxidations are, necessarily, more accurately controlled than those designed to produce the oxy-compounds and are typified by high temperatures and small amounts of oxygen.[1] Thus, one suggested process involves heating the saturated hydrocarbon (methane) under atmospheric pressure to a temperature of 1200°C. with a small amount of oxygen.[2] Under reduced pressure, the hydrocarbons may be heated with more than 10 per cent of oxygen (presumably by volume) but less than the amount required for complete oxidation.[3] Nitrogen oxides (NO_2, for example) which supply free oxygen at the high temperatures employed, may serve as the oxidizing agent used in converting saturated hydrocarbons to olefins, it is reported. The temperatures recommended in these processes are almost invariably high (in the neighborhood of 1000°C.). The oxygen content of the final mixture should range between 10 and 45 per cent by volume.[4] Winkler and Feiler[5] report that in general, in order to convert methane to acetylene, the hydrocarbon must be preheated to 1000-1200°C. or higher. Gases containing large proportions of methane mixed with its homologues (as in coke-oven gas) require temperatures in the range 800 to 900°C., but if the starting paraffinic hydrocarbon is largely propane and butane, a temperature of 500 to 800°C. is usually sufficient. The reaction tubes should be constructed of materials which will minimize deposition of carbon. These investigators suggest carbon silicide or other silicides for this purpose. In an example, 10 liters per hour of oxygen and 20 liters per hour of a mixture of methane homologues (ethane, 14 per cent, propane, 51 per cent, and butane, 12 per cent) were passed separately through heated silica tubes 2 mm. in diameter. Both the oxygen and the hydrocarbon mixture were preheated to about 700°C., the hydrocarbons being thus converted to olefins to the extent of about 36 per cent. The juncture of the heated oxygen with the olefin-containing hydrocarbon gas produced a short, extremely hot flame. The reaction gases escaped through an attached silica tube (2 mm. in diameter) at a very high velocity. The reacted gases were of the following composition:

---

[1] R. N. Pease and J. M. Morton (*J.A.C.S.*, 1933, **55**, 3190; *Chem. Abs.*, 1933, **27**, 4992; *Brit. Chem. Abs.* **A**, 1933, 1017) report that thermal decomposition of the hydrocarbons tends to crack first the paraffins, the olefins being more resistant. High temperatures increase the tendency toward olefin formation while the presence of oxygen prevents accumulation of hydrogen.

Nitrogen (present originally as impurity in the hydrocarbon gases)	3.2

OXIDATION OF OLEFINS

Dreyfus[6] reports that the degree to which an olefin is oxidized may be controlled by governing the conditions of the reaction zone and by lengthening or shortening the time of contact. For the production of ethylene oxide with a minimum of higher oxides, the optimum conditions are mild temperatures, short contact times, and employment of a catalyst having a basic reaction. A diluent such as carbon dioxide or nitrogen aids in suppressing the higher oxides, and ammonia or other volatile bases can be added to maintain the basic catalytic conditions. The production of acetaldehyde is favored by hydration catalysts such as phosphoric acid or zinc chloride at temperatures of 300 to 400°C. Acetic acid is the principal product if an excess of oxygen is used at relatively high temperatures with an active oxidation catalyst such as silver, copper, or their oxides.

Lefort[7] produced ethylene oxide, however, using temperatures from 150 to 400°C. and a powerful oxidation catalyst such as silver activated by copper, iron or gold. The reaction he proposes employs oxygen and steam as the oxidizing agents. Lenher[8] reports that the reaction producing ethylene oxide from ethylene by oxidation with oxygen is influenced by the surface of the reactor. The process can be carried on to some extent in a reaction vessel having a surface-to-volume ratio of not more than 4 to 1. The mixed gases are led through a packed-tube preheater where they are heated to 450°C. in contact with 4-mesh broken Pyrex glass. The effect of great surface-volume ratio in this preheater is to inhibit reaction almost completely, and the heated gases are then led into the reaction chamber proper which fulfills the requirement of low surface-to-volume ratio (Fig. 204). Here the reaction is said to proceed to yield about 20 per cent ethylene oxide, 65 per cent formaldehyde and acetaldehyde, and 3.2 per cent formic acid.

The ready reactivity of the double bond makes it possible to carry out a type of additive oxidation using substances other than the usual oxidizing agents. Carbon dioxide, and even carbon monoxide, normally a reducing agent, have been used with good results. Thus, Ramage,[9] using carbon dioxide and steam in the presence of an iron catalyst, produced alcohols from olefins. Larson[10] reports that carbon monoxide and ethylene can be combined in the presence of an acid catalyst, such as hydrochloric acid. The presence of oxygen in the reactants, however, leads to corrosion of the apparatus and deactivation of the catalyst, and tends to cause polymerization of the olefin. To remove the oxygen, this investigator proposes that the gases be passed through a solution made up of sodium anthraquinone-2-sulphonate, sodium hyposulphite and 30 per cent aqueous sodium hydroxide. In an analogous reaction, Carpenter[11] uses an inert diluent, such as nitrogen, and the mixture of ethylene, steam and carbon monoxide is reacted at 375°C. in the presence of phosphoric, boric or arsenic acid deposited on charcoal. Carpenter[12] also found that the undiluted gases can be reacted in the presence of acid salts such as zinc hydrogen phosphate or calcium dihydrogen phosphate [$Ca(H_2PO_4)_2$] or similar tungstic, molybdic or uranic salts. The reaction takes place at 325 to 350°C. under 200 to 700 atmospheres pressure. This ethylene-carbon monoxide-steam reaction to yield acids has been effected with other catalysts, e.g., chloroacetic acid,[13] silico-tungstic acid,[14] barium chloride,[15] carbon tetrachloride and activated carbon,[16] or activated carbon alone,[17] or by having the reaction take place in a chamber which is made of a 90 per cent silver alloy.[18] The reaction is aided also by leading the gases (under 700 atmospheres pressure) over a salt such as potassium carbonate which will react with the acid produced. A temperature of about 300°C. is recommended[19] in this operation.

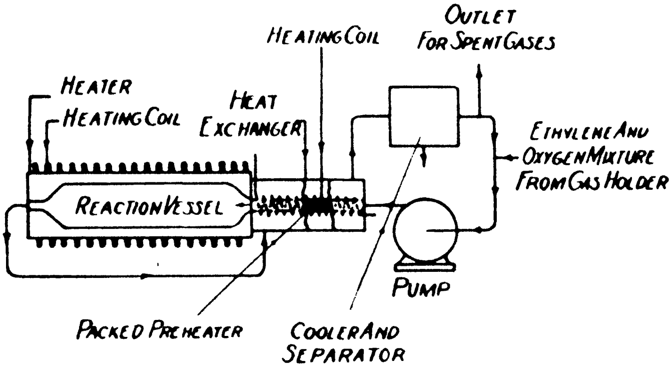

FIG. 204.—Diagram of Apparatus for Direct Oxidation of Olefins. (S. Lenher)

If aqueous alkali metal hydroxide is used, propene as well as ethylene can be made to combine directly with the hydroxide to form the metal acetate. Britton, Nutting and Huscher[20] suggest that the reaction in this case is:

$$CH_3CH{=}CH_2 + KOH + H_2O \longrightarrow CH_3COOK + CH_4 + H_2$$

Carried out at 365 to 375°C., the yield is said to be 30 per cent. In addition, a certain amount of isopropyl alcohol and polymers of propene are formed. Basic aluminum salts (e.g., potassium aluminate) act as catalysts in this reaction.

It has been proposed also that the oxidation be carried out in liquid medium. Whitmore, Homeyer and Trent[21] produced *ter*-butylacetic acid by passing diisobutylene through sodium dichromate and sulphuric acid and further oxidizing this intermediate product with a hypohalite such as sodium hypochlorite. Selenium dioxide reacts with cyclo-olefins to produce ketones, according to Schwenk and Borgwardt.[22] The reaction is carried out in solution under pressure. Thus l-menthene in ethyl alcohol is reacted with selenium dioxide to give an 85 per cent yield of a ketomenthene of the formula $C_{10}H_{16}O$. Riley[23] reports that the lower olefins (ethylene, propene, butene and amylene) react with selenium dioxide to form glyoxals or glyoxal polymers. The reaction takes place very readily, starting at temperatures as low as 50°C., and this investigator recommends 300°C. as the upper limit for successful reaction to form these substances.

Hydrogen peroxide effects oxidation of the double bond in a different way, in general leading to a hydroxylation, according to Milas and Sussman.[24] These investigators report that anhydrous hydrogen peroxide is stable in tertiary butyl alcohol for considerable periods, and can be kept for 6 months or longer at room temperature with little decomposition. The reagent was prepared by mixing the tertiary alcohol (400 cc.) with 100 cc. of 30 per cent hydrogen peroxide, and adding anhydrous sodium sulphate to bring about separation of water. The alcohol layer contained most of the peroxide and was further dried by anhydrous calcium sulphate. The addition of osmium tetroxide to the reagent thus prepared made it a highly active oxidizing agent which readily converted isobutene to isobutene glycol, trimethylethylene to trimethylethylene glycol, allyl alcohol to glycerol, and several of the unsaturated acids to the corresponding dihydroxy acids. As an example of the latter reaction, cinnamic acid was converted into phenylglyceric acid. From cyclohexene these investigators obtained adipic acid. On the other hand, Dupont and Dulou[25] were able to oxidize cyclohexene to cyclohexanediol. Quite similar to this method of oxidizing olefins is the procedure of Criegee,[26] who employed diethyl ether in place of butanol as reaction medium. The latter investigator, however, obtained aldehydes as main products. As an example of this oxidation, stilbene yielded benzaldehyde.

Ellis[27] has proposed that the mixed olefinic materials of the acid extract from cracked gasoline be treated with dilute nitric acid to effect the oxidation. The olefinic extract was added drop by drop to nitric acid (of 1.3 specific gravity). Considerable heat was generated by the oxidation, and the temperature was maintained between 30° and 40°C. Distillation of the oxidized material yielded first a light yellow, inflammable oil. This readily dissolved nitrocellulose, and its reaction with sodium sulphite solution indicated the presence of ketone material. The heavy end of the distillate was a darker oil, considerably less inflammable, and containing no appreciable amount of ketonic material. It was, however, found to be a fairly good solvent for celluloid. Pirlet[28] has suggested that nitrogen oxides be used as the oxygen carriers in oxidizing olefins.

THE MECHANISM OF ETHYLENE OXIDATION

Vaidya[29] has investigated the destructive oxidation of ethylene in flames by spectroscopic methods, and bands were found which indicated that CH and OH radicals were present. A system of fainter bands was investigated and tentatively assigned to HCO, though there is a possibility they result from a nitrogen-oxygen compound formed from the air in which the hydrocarbon burned. In the slow combustion of ethylene under atmospheric pressure at 300°C., Bone, Haffner and Rance[30] have found evidence that the process is a homogeneous reaction preceded by a definite induction period. During this induction period a small amount of aldehyde appears, but no peroxide. Experiments with the addition of nitric oxide or acetaldehyde as catalyst, along with oxygen, showed that as little as 1 per cent of the former substances eliminated the induction period and accelerated the subsequent reaction. Formaldehyde, although it shortens the induction period, does not affect the velocity of the final reaction. Ethylene oxide, on the other hand, has no effect on the induction period but retards the rate of reaction. Of the ethylene-oxygen mixtures tested, the most reactive proved to be one of 2 volumes of ethylene to 1 of oxygen, which gave ethylene oxide as the first product. It was concluded that the reaction proceeds as a series of hydroxylations, vinyl alcohol, $H_2C=CHOH$, being formed in the first step; this is transformed rapidly into an equilibrium mixture of the three C_2H_4O isomerides vinyl alcohol, ethylene oxide, and acetaldehyde,  $H_3C{-}\overset{O}{\overset{|}{C}}H$. Water vapor was found not to affect either the induction period or the rate of reaction appreciably. On the other hand, Steacie and Plewes[31] report a study of the effect of acetaldehyde on the oxidation mechanism of ethylene in which they found that the oxidation was not influenced by the presence of the aldehyde, and concluded that acetaldehyde was unimportant in the chain propagation of oxidation in ethylene-oxygen mixtures. Bone and Bell[32] made further investigations on the effects of water vapor on the slow combustion of ethylene-oxygen mixtures, and reached the conclusion that the oxidation is direct, with no intervention of steam. The gases were dried by treatment with phosphorus pentoxide, and the evidence tended to show that this intensive drying increased rather than diminished the reactivity of the gas mixtures both in slow and in explosive combustion.

Other oxidations of ethylene have been investigated, involving the presence of oxidants other than oxygen. Steacie and McDonald[33] tested the oxidizing properties of nitrous oxide atmospheres and believe that while this gas supports flame combustion, the nitrogen compound itself does not act as the oxidizing agent. On the other hand, it was believed that the decomposition product, atomic oxygen, was the active substance. It was found that ethylene-nitrous oxide mixtures had a higher ignition temperature than did ethylene-oxygen compositions. The latter mixtures react at a measurable rate at 300° to 450°C., although the nitrous oxide-ethylene reaction was slow even at 530°C. The latter reaction seemed to be an indirect oxidation of the polymerization and decomposition products of ethylene.

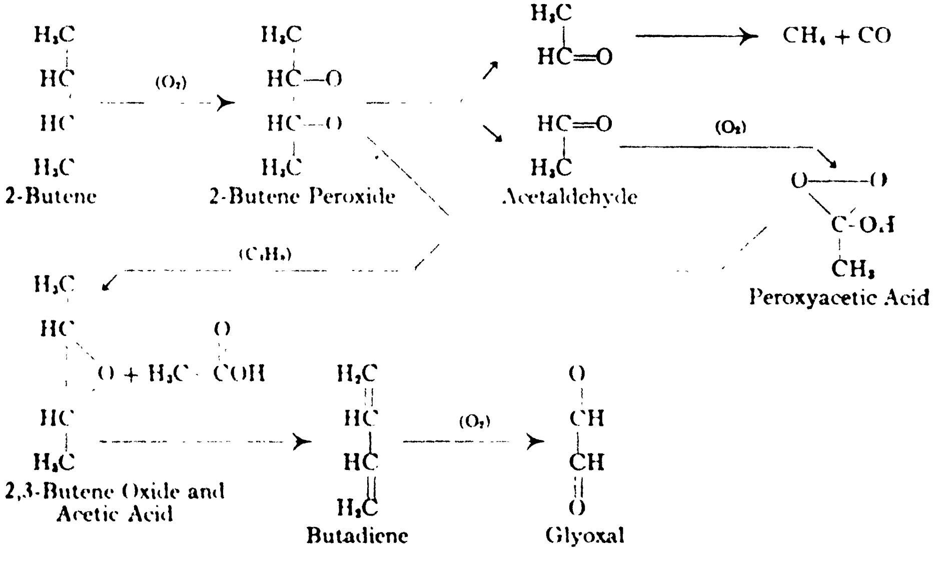
Barkhash[34] reports that although hydrogen peroxide does not ordinarily react with ethylene or pentene at room temperature, the addition of ferrous sulphate catalyzes the reaction and a mixture is formed, from which acetone, carbon dioxide, formic acid and acetic acid have been isolated. Aldehydes and higher homologues of acetone, propionic acid and glycols were not found, however.[35]

Oxidation Mechanism of Higher Olefins

Lucas, Prater and Morris[36] have attempted to determine the oxidation mechanism of 2-butene, as a typical example of the unsaturated hydrocarbons. If hydroxylation takes place at either of the two unsaturated carbon atoms, methyl ethyl ketone would be a reaction product. On the other hand, if oxidation occurs at both carbon atoms, dimethyl glycolic aldehyde or dimethyl glyoxal should result. When a mixture of 2-butene and oxygen (with the hydrocarbon in excess) was passed through a Pyrex tube at 375 to 490°C., the principal reaction products were acetaldehyde and butadiene. Other substances were also identified among the products. These included glyoxal, an olefin oxide, an acid and some peroxide. They believed that hydroxylation is not important, since no methyl ethyl ketone is formed. A reaction mechanism was proposed, as follows:



The butene, in addition, showed a tendency to polymerize to octene at the higher temperatures employed (490°C.).

Steacie, Hatcher and Horwood[37] studied the decomposition of glyoxal at temperatures between 410 and 450°C. and found that the substance disintegrates according to a first-order homogeneous reaction. Considerable carbon and tar were formed, and the results were erratic. They believed the transformation occurred about equally in three ways:

\end{aligned}
$$

They concluded that simple mechanisms previously suggested for the glyoxal decomposition were incorrect.

Hock and Schrader[38] found that two moles of cyclohexene take up 0.4 mole of oxygen in the course of 150 to 200 hours when exposed to light, about 20 per cent of the theoretical quantity for saturation. They report that the addition of a small quantity of eosin catalyzes the reaction so that it then proceeds at twice the former rate. Fractional distillation under reduced pressure yields, besides unchanged cyclohexene, as much as 19 per cent of the peroxide, $C_6H_{10}O_2$, and about 2 per cent of a peroxidic residue of a viscous, tarry nature. The cyclohexene peroxide dissolves (to the extent of about 5 per cent) in cold water to give a weakly acidic reaction. The solution becomes turbid on heating due to a reversible hydration reaction. In cold water, the peroxide adds water to form $C_6H_{10}(OH)(OOH)$, a substance which is unstable at the higher temperatures. If the 5 per cent aqueous solution is distilled under high vacuum, 2 per cent of the peroxide is recovered in the distillate. By titrating the distillate with stannous chloride-hydrochloric acid and ferric chloride solution, it was found that the dried distillate was 96 per cent peroxide. Heated with 2N sulphuric acid, the peroxide yields 50 per cent of *cis*-cyclohexane-1,2-diol and 10 to 20 per cent of cyclopentenealdehyde. Dissolved in cold sodium hydroxide and heated to 50°C. it yielded 60 to 65 per cent of 1-cyclohexene-3-ol. This same product can be formed by reducing the peroxide in aqueous sodium sulphite.

The photo-activation of olefin oxidation is of some technical interest, in that considerable amounts of unsaturated hydrocarbons are generally present in the oil sprays used in curbing insect pests on plants. Tucker[39] conducted a series of experiments which showed that the unsaturated substances are not toxic to foliage, but that the acidic substances formed by their oxidation are. At ordinary temperatures this slow oxidation takes place at a measurable rate only under the influence of light, and his experiments demonstrated that apricot leaves were not damaged by the oils when kept in the dark. However, a few days' exposure to the light brought about formation of "asphaltogenic acids" which were destructive. This investigator found that the presence of more than 0.5 per cent of these acids produced symptoms of poisoning. It was suggested that the acidic substances pass through the osmotic membranes of the cell walls of the leaf comparatively readily and break down within the cell to form colloidal asphaltic particles.

Despite the foregoing, Beatty and Edgar[40] reported that olefins do not always absorb oxygen more readily than do the corresponding paraffins. Under the conditions of their experiments, working with *n*-heptane, 1-heptene and 3-heptene, the data showed that heptane oxidized most readily of the three, 1-heptene next, and 3-heptene oxidized most slowly. A Pyrex glass furnace was used, the volatile fuel being mixed (in 2 per cent concentration) with air. The furnace was not

[39] R. P. Tucker, *Ind. Eng. Chem.*, 1936, **28**, 459; *Chem. Abs.*, 1936, **30**, 3575; *J. Inst. Pet. Tech.*, 1936, **22**, 272A. See also Chapter 51.

[40] H. A. Beatty and G. Edgar, *J.A.C.S.*, 1934, **56**, 107; *Chem Abs.*, 1934, **28**, 1656; *Brit. Chem. Abs.* **A**, 1934, 259.

run at steady temperature but was arranged in such a way that the temperature rose throughout the experiments at a rate of 2°C. per minute. Under these conditions, *n*-heptane began to oxidize at 244°C., the two heptenes at about 300°C. The maximum oxygen absorption was about 40 per cent of the theoretical in the case of each of the hydrocarbons, though the rate of oxidation varied widely. It was found, too, that there is a negative temperature coefficient of reaction velocity at higher temperatures (400° to 450° or 500°C.). The temperatures of inflammation, however, were not in the same order as the reaction velocities, that is, the l-heptene ignited most readily (at approximately 490°C.), the 3-heptene at approximately the same temperature that the *n*-heptane inflamed, 525°C. (See Fig. 205.)

Pigulevskii[41] investigated the oxidation of acetaldehyde and benzaldehyde, separately, in the presence of octene, and found that the latter acted as an inhibitor, or protector. Atmospheric oxygen was used, and although the oxidation of the aldehydes was inhibited, either of these substances acted as an activator in the oxidation of the unsaturated hydrocarbon. In studying the mechanism of these oxidations, the investigator found that peroxy-benzoic and peroxy-acetic acids, intermediates in the oxidation of benzaldehyde and acetaldehyde, respectively were active agents in oxidizing octene to octene oxide. Peroxyacetic acid oxidized octene more rapidly than it did acetaldehyde.

FIG. 205.—Relative Amount of Oxidation of Heptane and Heptenes as a Function of Temperature. (H. A. Beatty and G. Edgar)

The frequent experience that platinum oxide catalysts used in hydrogenating olefins must occasionally be shaken with air or oxygen in order to reactivate them is due, according to Thomson,[42] to the stimulating effects of olefin dioxides and other oxidation products formed. It has been generally found that pure olefinic material cannot be hydrogenated by a catalyst contaminated by traces of iron, but that impure olefins can be reduced when using such a poisoned catalyst. The experiments conducted showed that the reactivating effect was due to the acid oxidation products formed during the shaking with air, or to those present in the impure olefinic material. It is known that these substances oxidize readily in air, and an experiment was conducted in which trimethylethylene, freshly distilled over sodium, was hydrogenated by an iron-poisoned catalyst. It was found that the reaction stopped after 27 per cent of the theoretical amount of hydrogen had been absorbed. The percentage reduction could be increased by shaking the olefin, not the catalyst, with air or oxygen. The introduction of 0.001 mole of furoyl, benzoyl or succinyl peroxide reduced the time for 90 per cent reduction to roughly 40 or 50 per cent of the original time. The investigator believed that these peroxides were reduced to the corresponding acids, and it was found, in fact, that 0.002 mole of furoic, benzoic or succinic acid had an equally marked effect.

[41] V. V. Pigulevskii, *J. Gen. Chem.* (*U.S.S.R.*), 1934, **4**, 616; *Chem. Abs.*, 1935, **29**, 2145; *Brit Chem. Abs.* **A**, 1934, 1329.

[42] G. Thomson, *J.A.C.S.*, 1934, **56**, 2744; *Chem. Abs.*, 1935, **29**, 723; *Brit. Chem. Abs.* **A**, 1935, 192.

Various per-acids actively oxidize unsaturated compounds at the double bond, though the rates of reaction vary widely. Thus, Stuurman[43] reports that the reaction velocities of the lower olefins with peracetic acid range as follows:

Olefin	*Relative Reaction Velocity*
Ethylene	0.19
Propene	4.20
2-Butene	93.00
Isobutene	92.00
1-Pentene	4.30
2-Pentene	95.00
2-Methylbutene-2	1240.00
Cyclopentene	195.00
Methylcyclopentene	2220.00
Cyclohexene	129.00

Böeseken[44] and associates note that the rate of oxidation with peracetic acid is greatly influenced by the structural relationship between the alkyl groups and the double bond. Heptene-1 is much more slowly oxidized by peracetic acid than heptene-3 or 2-methylhexene-1. Diallyl is relatively slowly oxidized. Diolefins such as isoprene (2-methyl-1,3-butadiene) absorb the first oxygen atom very rapidly, but the second oxygen atom is taken up comparatively slowly. It was also reported that the velocity constant for the oxidation of ethylene by peracetic acid was almost too small to measure, but that of tetramethylethylene and peracetic acid was too great to be measured. The activating effect of alkyl groups introduced on the double-bonded carbons is strongly evidenced, although phenyl groups similarly placed tend to retard the reaction.[45] Böeseken[46] also reports that the rates of oxidation of double-bonded carbons in the presence of peracetic acid is greater than that of triple-bonded carbon. The triple bond appears to oxidize by way of the 1,2-diketone and the corresponding dicarboxylic acid. Some investigations conducted by Medvedev and Blokh[47] indicated that the peracid oxidation of cyclohexene is strongly influenced by the solvent used, although the rate depends more on the concentration of peracid than on the concentration of the olefin.

On the other hand, Guillemonat[48] reports that 2-ethylcyclohexene-2 may be oxidized by selenium dioxide in two steps without breaking the double bond. The hydrocarbon was oxidized by selenium dioxide in solution in acetic acid containing some acetic anhydride to yield 37 per cent of 2-ethylcyclohexene-2-acetate. Hydrolysis of this acetate yielded the unsaturated alcohol, 2-ethylcyclohexene-2-ol-1, and the double bond was still unbroken after a second oxidation which converted this compound to the corresponding unsaturated ketone. Similar oxidation of 2-methyl-2-butene yielded 2-methyl-2-butene-1-acetate which could be hydrolyzed to the unsaturated alcohol with the double bond still intact. Hydrogenation (by means of a platinum oxide catalyst) of this alcohol gave the saturated 2-methyl-1-butanol. Similarly, both 2-methylpentene-2 and 3-methylpentene-2 were oxidized to unsaturated alcohols, 2-methylpent-2-en-4-ol and 3-methylpent-2-en-4-ol.

Ozonolysis of Olefins

Although some oxidants are capable of selectively oxidizing olefin molecules at points other than the double bond, the action of ozone is said to be directed toward the unsaturated linkages. Church, Whitmore and McGrew,[49] in studying the dehydration of alcohols to produce olefins, used this reaction to trace the mechanism involved. Thus, dehydration of methylethylbutyl carbinol yields 55 per cent of 3-methylheptene-2, 30 per cent of 3-methylheptene-3, and 15 per cent of 2-ethylhexene-1, as indicated by the fact that the dehydration products, when ozonized, yielded proportions of the ketones which would be predicted from these unsaturates. The tendency of ozone to split the molecule at the double bond through the intermediate formation of an ozonide can be used in the determination of terminal $H_2C{=}CH$-linkages, according to Doeuvre.[50] A very dilute solution of the olefin to be tested is prepared, using ethyl acetate-acetic acid as the solvent, and the solution treated with ozone at -15 to $-20°C$. The ozonide is then reduced by sulphur dioxide and the formaldehyde which results is determined. Unsaturated compounds containing no terminal methylene groupings give only negligible amounts of formaldehyde. Similarly Clemo and Macdonald[51] report that although the decomposition of an ozonide of a molecule containing a vinyl grouping does yield formaldehyde, the reaction is not unique. Molecules which do not contain this structure may form ozonides which decompose to yield formaldehyde. However, where the vinyl group is present, some 10 times as much formaldehyde is formed. Hence, quantitative estimation of the aldehyde produced affords evidence for the presence of a vinyl residue, although qualitative estimation does not.

Pummerer[52] reports following the ozonolysis of unsaturated compounds by titrating the mixture at intervals with bromine. Thus, 3-ethylpentene-2 was dissolved in carbon tetrachloride, and bromine titrations made at short intervals showed that the olefin was saturated after 10 minutes' treatment with ozone in the apparatus used. In ozonizing cyclohexene under similar conditions, ozone treatment continued for 60 minutes before the bromine titration figures showed saturation. Mesityl oxide, on the other hand, required 45 minutes' operation before the bromine values showed any decline. This was believed to be due to the formation of a primary ozonide less saturated than the final product. When working with rubber and gutta percha solutions, the unsaturation, instead of decreasing, increased during the early part of the ozonolysis until a critical point was reached when the unsaturation values fell suddenly to zero. This fluctuation of values is, similarly, believed due to the formation of primary ozonides. It is suggested, too, that these primary ozonides are the sensitive, explosive substances formed during ozonization. Komppa[53] treated propenylbenzoic acid with ozone for 10 hours till bromine titration values indicated saturation. The ozonide thus formed was an unstable, partially crystalline compound melting at about 180°C. On standing, decomposition took place yielding 83 per cent of *p*-acetobenzoic acid.

Biphenyl does not form a hexaozonide, but Noller and Kaneko,[54] investigating this problem, have prepared 1-phenyl-1-cyclohexene and report that this compound readily adds 1 mole of ozone to the double bond of the cyclohexene ring. Furthermore, the 1,1′-dicyclohexene adds ozone to both double bonds. These investigators concluded that steric hindrance in the 1-1′ position is not the factor which prevents the formation of biphenyl ozonide. Noller, Carson, Martin and Hawkins[55] studied the ozone absorption rates of a number of compounds and report that oleic acid, methyl oleate and stilbene show rapid addition of 1 molecule of ozone to the double bond. The rate decreases considerably for triphenyl ethylene and compounds containing the grouping $-CH{=}CH-CO-$ (such as crotonic or cinnamic acid). Vinylacetic acid ($CH_2{=}CH-CH_2-CO-OH$) which has a similar, though slightly altered, grouping, shows an analogous, though lessened, retarding effect. A still further decrease was found with tetraphenylethylene and dichloroethylene. In compounds containing two or more double linkages (*e.g.*, diphenylbutadiene, sorbic and elaeostearic acids) rapid addition of one molecule of ozone takes place, but the rate then decreases sharply. In geometrical isomerides which undergo relatively slow addition, such as methyl fumarate and maleate, the *trans* form (the fumaric compound) reacts more rapidly.

OXIDATION OF ALKYNES[56]

According to Lenher and Kistiakowsky,[57] temperatures up to the explosion temperature may be used in the uncatalyzed oxidation of acetylene. These investigators report that formaldehyde, formic acid and glyoxal may be recovered from the reaction products obtained by passing acetylene and oxygen through a reaction tube at from 200°C. to the explosion temperature, though they recommend the range 275 to 316°C. as most desirable.

Steacie and McDonald[58] have investigated the uncatalyzed reaction of acetylene and oxygen and report that the rate of reaction is variable and dependent on the condition of the surface of the reaction vessel. It was found also that the order of the reaction is decreased in a packed vessel,[59] falling to 1.4. Although the ratio of carbon monoxide to carbon dioxide in the reaction products is, in the empty vessel, independent of pressure, in the packed vessel it is at the outset lower than in the empty chamber and falls even further with diminishing pressure. Addition of glyoxal has no appreciable effect on the rate of reaction; formaldehyde, however, decreases it. It was concluded that the oxidation was a chain reaction, the chains being initiated at the walls of the vessel but not destroyed there. The following mechanism was proposed:

[59] This indicates that the velocity constant is less than that for a second order, but greater than that for a first order reaction. For a discussion of orders of reactions, see Chapter 20.

$$C_2H_2 \xrightarrow{O_2} (C_2H_2O_2) \rightarrow CHO{-}CHO \xrightarrow{O_2} CHO{-}COOOH$$

$$CHO{-}COOOH \left\langle \begin{array}{l} \xrightarrow{(+CHO-CHO)} CHO{-}COOH \rightarrow HCHO + CO_2 \\ \xrightarrow{(+HCHO)} HCOOH \rightarrow CO + H_2O \end{array} \right.$$

According to Lenher,[60] the oxidation of acetylene is catalyzed by the presence of a small quantity of nitric oxides. The presence of this catalyst (4 or 5 per cent) allows the reaction to take place at a considerable rate at a lower temperature. For example, if acetylene (in slight excess) is mixed with oxygen, and 4 to 5 per cent of water vapor and 4 to 5 per cent of nitric oxide added, the reaction takes place at a temperature as low as 170°C. However, 230°C. is recommended, since under these conditions a yield of 21 to 23 per cent of glyoxal is obtained with a contact time of 2 minutes. On the other hand, Heckel and Nashan[61] report that a mixture of acetylene, air and nitric oxides can be reacted at 300°C. to yield acetaldehyde and acetic acid.

Young, Vogt and Nieuwland[62] studied the reactions of the alkyne peroxides and report that the oxidizing properties of these peroxides are in all respects similar to those ascribed to the olefin peroxides. Studies of butylacetylene and analogous compounds showed that the dialkylacetylene forms compounds of a peroxide nature as readily as a monoalkylacetylene. Butylacetylene that had been exposed to the air for about six months gave a good aldehyde test with Schiff's reagent and had a pronounced acid reaction. When a small amount of butylacetylene was allowed to evaporate at room temperature, the residue had a strong odor of valeric acid, although the amount of acid formed was too small to allow of chemical isolation. However, when the alkyne was maintained at 35 to 45°C. for three months, it was found that the peroxide concentration increased rapidly during the first three weeks and remained constant thereafter, while the concentration of valeric acid, on the other hand, increased steadily throughout the experiment. The results were believed to indicate that after a few weeks the rate of formation of the peroxide was approximately equal to the rate at which it oxidized the alkyne, the peroxide being destroyed in the latter step. At the end of the three-month period of heating, titration with standard potassium hydroxide and phenolphthalein showed an acid concentration 2.12 normal. In the meantime, the color of the butylacetylene had progressively changed from water-white to reddish brown.

In an effort to isolate the peroxide, a quantity of the oxidized butylacetylene was distilled through an efficient column. When most of the butylacetylene had been removed, the residue suddenly began to fume and darken, with the evolution of considerable heat. After a few minutes the reaction subsided, leaving a viscous, dark brown and strongly lachrymatory acidic residue. The peroxide appears to be highly unstable when in concentrated form.

It has been suggested that alkynes behave as do the alkenes[63] in oxidation, i.e., that two OH groups first add at the unsaturated bond. Krestinskii and Kelbovskaya[64] attempted to derive some experimental proof of this possible reaction which, with acetylene, should yield the glycol, HOHC=CHOH, at once hydrated to $HOCH_2$-$CH(OH)_2$, and the latter in turn can yield oxalic acid, acetic acid and similar compounds. Acetylene, phenylacetylene, methylethylacetylene and 2,2-dimethylbutyne-3 were studied. Special attention was given to the isolation of any neutral products, and the oxidizing agent (in this case potassium permanganate) was added in very dilute solution at 0°C. to an excess of the hydrocarbon. However, no neutral reaction products could be detected; only acids appeared, cleavage occurring at the triple bond. Acetylene gave formic acid and presumably traces of oxalic. Methylethylacetylene yielded acetic and propionic acids, phenylacetylene gave carbon dioxide, benzoic acid and traces of formic. The 2,2-dimethylbutyne-3 formed 3,3-dimethylbutyric acid.

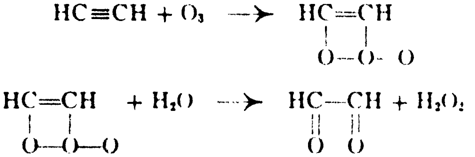
Acetylene itself reacts with ozone to produce formic acid and glyoxal, but according to Hurd and Christ[65] this is an almost unique case in that most of the alkynes are split at the triple bond by ozonization. However, the reaction has been used to prove the location of the triple bonds in 6,10-hexadecadiyne and in 6,9-pentadecadiyne. Caproic and succinic acids were formed from the latter substance; caproic and malonic from the former. Hurd and Christ investigated the ozonolysis of six acetylene representatives, phenylpropiolic acid, phenylacetylene, 1-hexyne, 1-heptyne, ethinylcyclohexanol and ethinylfenchyl alcohol. In each case, splitting occurred at the triple bond yielding from 42 to 61 per cent of the acids. In the case of 1-heptyne, accurate determinations of both acids showed that two acids (formic and caproic) had been formed in equal quantities, totaling 59.2 per cent. However, despite the fact that a large excess of ozone was employed, no further production of acids took place. These investigators favor the following mechanism in the ozonization and subsequent hydrolysis of acetylene:



$$HC\equiv CH + O_3 \longrightarrow \begin{array}{c} HC{=}CH \\ |\quad\;| \\ O{-}O{-}O \end{array}$$

$$\begin{array}{c} HC{=}CH \\ |\quad\;| \\ O{-}O{-}O \end{array} + H_2O \longrightarrow \begin{array}{c} HC{-}CH \\ \|\quad\;\| \\ O\quad\;O \end{array} + H_2O_2$$

Chapter 40

Autoxidation of Petroleum Distillates. Gum Formation

The phenomenon of autoxidation has attracted the interest of many workers It has been defined as the combination of a whole molecule of oxygen with an oxidizable substance to give a primary peroxide which may then change in a number of ways to yield stable oxidation products.[1] This means that 1 molecule of an autoxidizable substance (A) reacts with a molecule of oxygen to furnish the peroxide AO_2. Such peroxides are formed with the absorption of energy and may then decompose to yield various products or react with other molecules of the autoxidizable substance.

Many substances may undergo autoxidation, among them being phosphorus and sulphur compounds, sodium bisulphite, benzaldehyde, paraffin, petroleum distillates, rubber and turpentine.[1a] Catalysts may also play a very large part in such phenomena. Thus, Suzuki[2] showed that oxides and some salts of lead, cobalt and manganese exert a stronger effect on the oxidation of *d*-α-pinene than do the oxides of platinum, silver, chromium or thallium. Furthermore, the oleates of lead, cobalt and manganese are more active catalytically than the corresponding stearates or sulphates. Temperature is also an important factor in many instances. For example, above 40°C. oxidation of pinene yields verbenone and verbenol and polymerized substance, whereas below 20°C. the product is a viscous mass consisting mainly of the peroxide.

AUTOXIDATION OF HYDROCARBONS

Among autoxidizable substances which lend themselves to study, tetralin (tetrahydronaphthalene) has received considerable attention because of the ease with which its peroxide may be isolated.[3] The latter may be obtained by extracting aged tetralin (i.e., a sample which has been stored in contact with air) with caustic soda,[4] or by bubbling air through tetralin heated to 75°C. and removing the unreacted hydrocarbon by distillation at reduced pressures.[5] Since the study of tetralin peroxide gives some insight into the nature of the intermediate products of autoxidation, it is of interest to discuss some of its properties.

Tetralin peroxide melts at 56°C. It is stable for a short time at 120 to 125°C. and loses water at 130°C. Above this latter temperature it explodes. Treated with potassium permanganate it furnishes β-*o*-carboxyphenyl propionic acid:

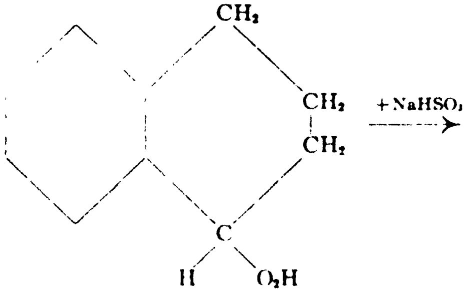
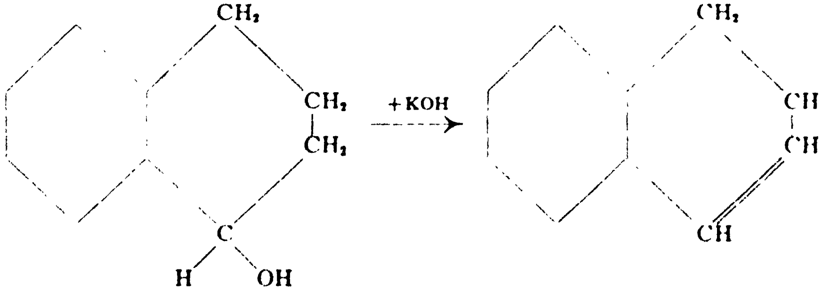
The peroxide is reduced by potassium iodide in aqueous acetic acid, or better by sodium bisulphite in aqueous methanol, to give tetrahydro-α-naphthol. The latter loses water when treated with freshly melted potassium hydroxide and forms 1-2-dihydronaphthalene. Warm caustic soda solution (*2N*) converts the peroxide into 1-ketotetrahydronaphthalene.





Tetralin peroxide reacts with iron carbonyl to give a dark red coloration and liberate gas.[6] It darkens mercury and prevents sulphur in liquid fuels from discoloring copper, according to Kiemstedt.[7]

The formation of tetralin peroxide is not affected by light or contact substances.[8] Tanaka, Kuwata and Aoki[9] studied the effect of phenols and naphthols on the autoxidation of tetralin and found the inhibiting power of phenol was decreased by the introduction of methyl, nitro or chloro groups. Polyhydroxybenzenes and naphthols, however, were powerful inhibitors. Amines were less effective than the corresponding hydroxy compounds, and alcohols, aldehydes, ketones and acids showed no effective inhibition.

Decalin (decahydronaphthalene) forms autoxidation products more slowly than tetralin.[10] Castiglioni[11] reports that light, especially ultraviolet, accelerates this reaction. By noting changes in acidity, the degree of oxidation may be determined[12] for a particular set of conditions. However, the addition of 0.001 to 0.01 per cent of pyrogallol, hydroquinone or α-naphthol is said to retard the autoxidation of decalin very markedly.[13] Other hydrocarbons found to undergo autoxidation are unsaturated cyclic compounds as 1-methyl-1-cyclohexene and 1-methyl-3-cyclohexene.[14]

Catalysis of Autoxidation Reactions

Arditti[15] noted that there is an induction period in the absorption of oxygen by normal hexadecane which is decreased by higher temperatures. The rate of absorption increased rapidly after the initial induction period and then diminished nearly to zero. The first product of oxidation by the absorbed oxygen was carbon monoxide, while later the dioxide was also formed. An amount of hydrogen and methane proportional to the oxygen absorbed was formed. This same investigator[16] studied the effects of several substances on the oxidation of paraffin oil by oxygen bubbled through it at 130°C. and found that copper, nickel, nickel oxide and cupric oxide catalyzed the reaction, whereas aniline, *n*-hexadecane, ferric oxide, phenol and water inhibited it. Dupont[17] determined the catalytic effects of acetylacetone and various metallic acetylacetonates on the autoxidation of 1,4-dimethylcyclohexane and phenylcyclopentane. He reported that the order of decreasing activity of metal-acetylacetone complexes in either case was cobalt(ous and ic), copper, manganese, iron and cerium. In the experiments on phenylcyclopentane allowance was made for the fact that this substance absorbs oxygen spontaneously. Dupont believed that the oxidation of these hydrocarbons was autocatalytic to a certain extent, but that catalysis also played a part.

Stephens[18] noted that autocatalysis played an insignificant part in the autoxidation of cyclohexene at 28°C. The hydrocarbon was purified rigorously and it was shown that the induction period decreased with increasing purity, but did not disappear even with the most highly purified material. Arsenic trioxide, which is occasionally present in glassware, was an inhibitor. He concluded that the induction period was caused by inhibitors present in minute amounts.

Gum in Gasoline

The autoxidation of gasoline has been the object of extended study by many investigators[19] because of its formation of gum, the latter being a deleterious com-

[a] Oxidized by oxygen under pressure until a 20 pounds per sq. in. (1.4 kg. per sq. cm.) pressure drop occurred.
[b] For gasoline used in elementary analysis the time was not specified. It was 86 days for the other samples.

ponent when present in sufficient proportions in motor fuels.[20] Of the unsaturated hydrocarbons present in cracked distillates, diolefins are particularly prone to gum formation.[21] The oxidation-polymerization of unstable constituents of the gasoline is thought to form gasoline-soluble colloids which coagulate and become gasoline-insoluble. This statement is supported by the respective compositions of gasoline-soluble and -insoluble gums which average about 70 per cent carbon, 7 per cent hydrogen, 21 per cent oxygen and 2 per cent sulphur and ash in each case.

The gum remaining after the evaporation of oxidized, cracked gasoline was studied by Morrell and co-workers.[22] They oxidized the gasoline in steel bombs[23] at an initial pressure of 135 pounds and a temperature of 100°C. Oxidation was stopped 10 minutes before the beginning of the rapid oxygen absorption and after the pressure had dropped 5, 10, 20 and 50 pounds by running cold water around the bomb. Analysis was made of the gasoline from each experiment by concentrating it by evaporation under about 2 mm. pressure at 79°C. The vapors were condensed by passage through an ice-bath and afterwards by an acetone and carbon dioxide mixture. This gave three fractions, i.e., a residue and two condensates, each of which was studied. These investigators found that the residue contained peroxides, aldehydes and acids and that these products were present in practically the same proportion regardless of the state of oxidation.

The products formed by oxidation under pressure and at slightly elevated temperatures (accelerated oxidation) differed somewhat in the specific compounds present from those formed during storage, but only slightly in elementary composition as is shown by some of the data of Morrell and co-workers in Table 184.

In the former case, peroxides and acids were present in the greatest amount in the residue and light fractions, respectively, whereas all oxygen-containing products were present in greatest amount in the residue from stored gasoline. Oxidation was accelerated by evaporation in a copper dish, and on reaching dryness peroxides were largely decomposed. These investigators concluded that peroxides represent the first step in gum formation and are essential to it, although acids and aldehydes may have some significance since the insoluble mass

which sometimes precipitated during oxidation has a high acid content. The formation of peracids during the storage of gasoline derived from sapropelite, was shown by Karavaev and Kuruindin.[24] In this instance the stock had been previously treated with sulphuric acid and distilled over sodium.

According to McNamara[25] certain treatments, such as vapor phase refining with zinc chloride, hydrogenation, or blending with straight-run gasoline, increase the induction period whereas doctor-treating and sunlight accelerate oxidation. He also states that a rise in temperature of 20°F. roughly trebles the rate of gum-formation.

Shchitikov[26] found that thorough washing with water considerably improved the color and decreased the potential gum content and acidity of a cracked distillate after preliminary neutralization. He recommended two caustic treatments before redistillation. He also stated that the stability is lower and the gum formation higher when the finished cracked gasoline is treated with sodium hydroxide or sodium carbonate. Gerr and co-workers[27] pointed out that the diolefins which caused the instability of cracked gasoline were removed by refining. They observed that the higher boiling fractions were the more stable, but that all fractions needed refining. The gasoline obtained by treatment of the cracked distillate from Emba crude oil with kerosene acid sludge, followed by neutralization and distillation is reported to be very unstable.[28]

Weller[29] observed that a blended fuel containing 10 per cent alcohol had a 50 per cent shorter induction period than the original fuel, but he did not regard the induction period as conclusive in the determination of stability of fuels to gum formation. Conrad[30] showed that different tests may give widely varying results and fail to indicate the behavior of the fuel when kept for long periods of time. For example, the copper dish and Hunn bomb tests failed to give values which corresponded to gum-formation occurring during storage of the fuel for 10 months. He also demonstrated that the relative amount of gum formed on storage was not a linear function of the time. Gasoline with an induction period of 240 minutes, or potential gum of 50 mg. or less, is reported to be satisfactory in normal storage for periods of less than 1 year.[31]

DETERMINATION OF GUM

Efforts to ascertain the degree of gum formation in gasoline have resulted in several methods for the estimation of both potential and existent gum.[32] One of the oldest is the well-known copper dish. Since the results obtained by this procedure are not reproducible with accuracy because of the catalytic action of the metal, it has been modified by employing a glass or porcelain dish. The rate of evaporation is frequently increased by directing a jet of air towards the center of the sample.

For determination of the actual gum present in cracked gasoline, Woog, Givaudon and Dacheux[33] suggest evaporation of the sample at slightly elevated temperatures in an apparatus arranged so that steam from a water-bath (the heating medium) cannot come in contact with the test dishes. They give the following details: A Pyrex dish is thoroughly cleaned and dried at 160°C. for 45 minutes. After being cooled at least 2 hours in a desiccator and weighed to 0.1 mg., 100 cc. of gasoline are added and evaporated in the apparatus for 3 hours. Afterwards the dish and any residue are dried in an oven for 6 to 8 hours at 160°C., or if the residue is wet it is first dried at 100°C. for 2 hours and then at the higher temperature. The dish is cooled for at least 2 hours in a desiccator and weighed. Gasoline which contains less than 10 mg. of gum per 100 cc. causes no trouble in an engine.

Engine conditions were simulated by drawing atomized gasoline and air through a horizontal aluminum tube containing an aluminum helicoid. This was maintained at 105 to 110°C. in an electric oven. During the course of 5 hours, the vapors from 1100 cc. of gasoline were drawn through this apparatus by a vacuum of 20 mm. The amount of gum formed by this procedure showed a definite relationship to the "actual" gum as determined by the above evaporation test.

For estimating potential gum, Woog, Givaudon and Dacheux recommend that the sample be exposed to ultraviolet light for 30 to 60 minutes and then heated under pressure with oxygen at 100°C. for 2 to 3 hours. The resulting gum is then determined by evaporation of the treated liquid. Thomas,[34] on the other hand, considers subjecting the sample for 20 minutes to the action of oxygen at 100°C. under 10 pounds pressure as sufficiently vigorous treatment.[35]

Freund[36] developed a method for estimating gum in which the sample was placed in a quartz tube and exposed to the light of a standardized mercury-vapor lamp for 10 minutes at 15 to 25°C. Gum formed by this procedure and by oxidation differed largely in respect to oxygen content. The type of atmosphere in which

the gum was dried also had some influence on the oxygen content. Table 185 shows some of his data for samples of a gasoline derived from a Dubbs-cracked Moreni crude oil.

From this it is evident that the highest oxygen content occurs in gum formed by oxidation in a bomb. When the gum was dried in an atmosphere of nitrogen, the composition showed somewhat less oxygen than if dried in air. However, the relative proportion of carbon and hydrogen in the gum was practically independent of the manner of formation. Mardles and Moss[37] incubated gasoline samples prior to the determination of existent gum by storing them at 35°C. for 20 hours in the dark. The usual sample was 50 cc. in a 500 cc. long-necked, glass-stoppered flask. The gum found (by evaporation in a glass dish) after this treatment corresponded rather closely to that formed after 3 months' storage, as is shown in Table 186.

TABLE 186. - *Comparison between Potential Gum Test and Gumming During Storage.*

	Gum Increase in mg. per 100 ml.

Low temp. coal distillate (B)	3	5
Cracked distillate	40	20
Vapor phase cracked distillate	55	65
Hydrogenated coal distillate	1	1

These investigators suggested that the test may be accelerated still further by increasing the temperature to 50° or 75°C.

Treatment of 20 cc. of gasoline in a Dewar flask with a 20 per cent solution of stannic chloride and measuring the rise in temperature was suggested by Kogerman[38] as a procedure for determining the instability of a motor fuel. This method, however, is not applicable to fuels containing alcohols.

The standard methods of the American Society for Testing Materials[39] and the Institute of Petroleum Technologists[40] depend upon a current of air blowing across the sample while evaporation is taking place. The comparison of these tests given in Table 187 is of interest.

Bridgeman[41] found that by using a sufficient air flow over the gasoline sample during determination of gum by the usual methods, the other factors which often affect the results, such as the volume of gasoline evaporated, the concentration of gum-forming constituents and the temperature of evaporation, had very little effect. The same values for gum were obtained whether the air flow was 320 or 680 ml. per second.

A rapid titrometric method for the estimation of gum has been proposed[42] which comprises distillation of the sample and titration of the residue. The recommended procedure is: Distil 100 cc. of the sample in an Engler flask on an oil bath at 160°C., at atmospheric pressure, for 15 minutes and then under vacuum which

TABLE 187.—*Comparison of Standard Tests for Gum.*

	ASTM Specifications	IPT Specifications
Sample container	Beaker, one size only (100 ml.)	Hemispherical dish Size a-25 cc. sample (6 cm. dia., 3 cm. height) Size b-50 cc. sample (9 cm. dia., 5 cm. height)
Heating medium	Closed bath of 3 per cent water in ethylene glycol	Open steam bath
Temperature of evaporation	160-165.8°C.	100°C.
Flow of air	One liter per second over the entire surface	Jet impinging at one point. For 25 cc. sample air pressure equivalent to 1 cm. of water. For 50 cc. sample air pressure equivalent to 2 cm. of water.
Temperature of the air	Preheated to 151.7-160°C.	Cold
Quantity for test	50 cc.	25 or 50 cc. depending on gum content
Time for evaporation	About 30 min.	60 min. or more

is so regulated that the distillation is resumed at the rate of 2 drops a second. After 5 minutes the vacuum should reach 30 to 50 mm. of mercury and should be so maintained until the end of this operation. The residual gum is dried by continued heating (under reduced pressure). The total time for distillation and drying should be 40 minutes. After cooling and blowing oil from the neck of the flask, the gum is dissolved in 15 cc. of carbon tetrachloride and titrated in the following manner. To the solution are added 15 cc. of 20 per cent sulphuric acid and 20 cc. of 0.1*N* potassium permanganate, all of which is then heated over a direct flame and agitated for 3 minutes after the solvent starts to boil. Then 2 cc. of a solution of 25 g. potassium iodide in 100 cc. of water, 10 cc. of 0.1*N* sodium thiosulphate solution and 1 cc. of starch solution are added and the excess potassium permanganate determined. One milligram of gum is equivalent to 1 cc. of 0.1*N* potassium permanganate.

Egloff and co-workers[43] have investigated and discussed various procedures for determination of gum content and concluded that none is wholly satisfactory. They state that the air-jet method gave some correlation between experimental results and gum deposition in motor cars. Further that the copper-dish test was of value in predicting storage stability, particularly if considered in conjunction with the oxygen bomb test.[44]

INHIBITION OF GUM FORMATION

Because the addition of antioxidants increases the induction period in gum formation, and because it protects the gasoline for some time from various oxidative changes, many workers have advocated the use of oxidation inhibitors in gasolines.[45] It is well known that cracked distillates give gasolines which are superior in many performance characteristics to the analogous straight-run fractions when used similarly.[46] The presence in these cracked motor fuels of many conjugated and other diolefins makes them susceptible to oxidation and the formation of gums. However, incorporation of inhibitors ameliorates these tendencies to a considerable extent. Rogers and Voorhees[47] observed that the solubility of an inhibitor should be less in water than in gasoline. Many useful inhibitors, such as catechol, hydroquinone, pyrogallol and benzyl-*p*-aminophenol are not very soluble in gasoline. Thomas[48] has overcome this difficulty by dissolving them in cresol and adding this solution to the fuel. He found that the above compounds were the most effective of some sixty substances investigated.

[44] The determination of gums dissolved in kerosene and cracked kerosene distillates are given, respectively, by B. K. Tarasov and V. V. Rudenko (*Groznenskii Neftyanik*, 1934, **4** (1), 65; *Chem. Abs.*, 1935, **29**, 2720; *Brit. Chem. Abs.* **B**, 1935, 1032) and L. A. Aleksandrov (*Groznenskii Neftyanik*, 1934, **4** (1), 66; *Chem. Abs.*, 1935, **29**, 2720; *Brit. Chem. Abs.* **B**, 1935, 1032).

[45] See, for example, *Chem. Trade J.*, 1935, **97**, 25, 49, 69, 115, 133; *J. Inst. Pet. Tech.*, 1935, **21**, 414A. See also Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., Inc., New York, 1934.

Lowry and co-workers[49] reported results obtained by using various dyestuffs as inhibitors of gum formation. Indophenol and leucoindophenol were the best of those tried. In almost all cases azo-dyestuffs were inferior to the phenols from which they were prepared.

These investigators found that it was possible to estimate colorimetrically the extent to which an inhibitor had become exhausted if there was present a dyestuff with inhibiting power. Although not strictly accurate, a rather close approximation was possible on the assumption that both the dyestuff and inhibitor were consumed at the same rate so that their relative amount would always be constant. As an example, they reported an experiment in which phenylazo-α-naphthol and α-naphthol were used; the results are shown in Table 188. Although the figures do not check very closely, they are in sufficient agreement to be of some interest. Another example of a colored substance which has been used to follow the course of the depletion of inhibitors is rubrene.[50]

[a] Determination of α-naphthol made by reaction with 2,6-dibromoquinone chlorimide.

ganic substances has been outlined by Lowry[52] and Egloff and co-workers.[53] The presence of an easily oxidizable group, such as aromatic hydroxy or primary or secondary amino groups, or multiples of these, as well as alkyl, aryl or tertiary amino groups, ortho or para to the amino or hydroxy groups, gives increased inhibiting power. The presence of nitro, carbonyl or carboxyl radicals has the opposite effect. Egloff, Morrell, Lowry and Dryer proposed that the antioxidant be added to the gasoline before the latter has been exposed to air. Other methods in which the antioxidants may be added have been suggested.[54] Thus, the cracked gasoline may be treated with acid, redistilled and the antioxidant incorporated. It may be clay-treated before adding the inhibitor, or the inhibitor may be added to a cracked fraction, which is then blended with the main body of the fuel.[55] Mardles[56] found that the inhibiting power of substances varied in different fuels and in different concentrations. Bickmore[57] recommended, therefore, that the specific inhibitor and its optimum concentration be determined for a fuel. Furthermore, he reported that most of the gum-forming substances can usually be found in the fraction boiling between 86° and 116°C. Degtyarèva[58] reported that hydroquinone was the best inhibitor and pyrogallol next best.

Sager[59] has isolated an inhibitor, consisting of *p*-cresol, by acidifying the caustic soda wash from a Rumanian cracked distillate. It was less effective than the commercially available cresol but also much less expensive. Lowry and Dryer[60] inhibited autoxidation by the addition of tars formed during the destructive distillation of wood. The fractions of lignite[61] and coal tar[62] boiling from about 200 to 300°C. have been used for the same purpose. Benedict[63] proposed to add the reaction product from an alkyl amine and wood tar or an aliphatic acid to gasoline.

Sloane and Wasson[64] recommended the addition of a naphthenic hydrocarbon which has a kauri-butanol value above 15 as a gum flux for any fuel with a high potential gum content. Phosphatides are proposed also as inhibitors.[65]

Aliphatic amines have been recommended by many investigators. Burk[66] suggested the formation of an amine *in situ* by the interaction of ethylene dichloride and ammonia in solution in the gasoline at temperatures above 200°F. The addition of 0.002 per cent or more of a polybutyl or amyl amine, or 0.05 per cent of di- or triethanolamine, has been suggested.[67]

Various derivatives of the lower aliphatic acids, such as the amino and oxamic acids, urethanes,[68] *p*-hydroxyacetonitrile[69] and *p*-hydroxyphenylglycine[70] have been proposed as inhibitors in motor fuel. Esters of dibasic acids, such as diethyl maleate and dibutyl phthalate, are reported to retard the deterioration of cracked gasoline.[71]

Diarylguanidines[72] and their salts with various aliphatic acids[73] have been added to gasoline as antioxidants. The salts may be employed also with higher boiling fractions, such as lubricating and transformer oils, containing unsaturated hydrocarbons. The addition of imides, e.g., succinimide, phthalimide or its ethyl or phenyl derivatives, to cracked hydrocarbon distillates containing high proportions of unsaturates has been suggested.[74] Other inhibitors include semicarbazides and solutions of them,[75] monoalkyl or monoaryl hydrazines, and also acyl derivatives of aliphatic amines, diamines and secondary amines,[76] and certain substituted aromatic amines[77] and amides.[78]

According to Whyte[79] 1 per cent of a cyclic ketone, such as cyclohexanone, will stabilize a benzene-gasoline fuel.

A solution of phenol in cresol has been added to the more unstable fraction of a cracked gasoline after the fraction had been refined separately.[80] The other fractions were then blended with the stabilized lighter fraction. Phenol, cresols, guaiacol, anthracene and phenanthrene have been reported as "anti-catalysts" to render gasoline "gum and cloud free."[81] Other phenolic compounds, such as benzyl-*p*-aminophenol, pyrogallol or α-naphthol,[82] xylenols,[83] or *ter*-alkylated phenols,[84] aminophenols,[85] tetra-alkylphenols,[86] diaminophenols,[87] cyclohexylaminophenols,[88] benzylaminophenol,[89] 5-benzylamino-2-cresol,[90] 5-amino-2-hydroxytoluene,[91] amino-phenolic compounds, as 8-amino-1,4,5-trihydroxy naphthalene,[92] acylaminophenols,[93] benzylmethyl-, dibenzyl-, benzylidene-, cinnamylidene- and *o*-chlorobenzylidene-amino-phenol[94] have been suggested as antioxidants. Benzylaminophenol is added to fuels rendered unstable by lead tetraethyl.[95] A method for adding benzylaminophenol (dissolved in alcohol) to motor fuels has been proposed by Wagner.[96] Amino- and amino-hydroxy-phenones[97] and certain ethers, such as *p*-methylamino-*p'*-amino diphenyl ether,[98] are reported to be inhibitors.

Polyamines, such as *o*- and *p*-phenylenediamine,[119] tolylenediamines,[120] diaryl arylenediamines[121] and diaminodiphenylamine,[122] are said to be effective antioxidants. Gasoline which has been partly refined with sulphuric acid may be protected from oxidation by the addition of substances containing an aromatic polyamine radical.[123]

Pyridine or picolines,[124] phenoxazine,[124a] azoxybenzene, hydrazobenzene,[125] aminoazo- and hydroxyazo-benzenes[126] have been proposed as gum inhibitors.

Ayres[127] has suggested the use of triphenyl phosphate, benzidine, α-naphtholbenzein, xylidine, and lead or calcium sucrate. Amine salts of hydroxy aromatic hydrocarbons have also been proposed.[128]

A solution of α-naphthol and aniline in ether prevents deterioration of cracked gasoline.[129] The addition of α-naphthol and phenyl-β-naphthylamine to a motor fuel not only retards the induction period but also lowers the rate of gum formation.[130] Dihydroxynaphthalenes,[131] 1,4-dihydroxyanthraquinone,[132] 1,2-dihydroxyanthraquinone,[133] α-naphthol and α-naphthylamine, aryl-amino-naphthalenes,[134] acetone anil,[135] aldol-α-naphthylamine[136] and 1,8-epoxynaphthalene[137] are gum inhibitors.

Some of the higher hydrocarbons, such as anthracene and phenanthrene, are antioxidants.[138] Gum formation in fuels which are rendered unstable by organometallic compounds may be inhibited by the addition of naphthols, naphthylamines, polyhydroxybenzenes,[139] hexadecylphenyl acetylene,[139a] dinaphthylene oxide or dioxide or perylene.[140] Amino and hydroxy derivatives of phenanthrene, chrysene, picene,[141] dihydroxy, dihalo, dicyano and dibenzyl derivatives of perylene[142] and diamino and dihydroxy derivatives of fluorene[143] have been used to inhibit autoxidation. The following substances have also been suggested: camphor, camphorone, camphoric acid,[144] hydroxyquinolines, hydroxytetrahydroquinolines,[145] thiodiarylamines,[146] substituted aryl arsine or stibine oxides[147] and N-(hydroxyaryl)-morpholines,[148] unrefined corn oil,[149] nascent hydrogen[150] and aliphatic-amine salts of hydroxy-aryl compounds as hydroquinone dianilide.[151]

It has been found that petroleum distillates can be stabilized in the vapor phase at about 300-500°C. in contact with catalysts of sulphides, selenides or tellurides of metals from groups 6 to 8 of the Periodic Table.[152]

Dyestuffs of several types, such as dyes of the oxazine-, indamine-, eurhodine-, safranone- or aposafranone-base groups, have been used in conjunction with amino or phenolic inhibitors in gasoline of normal gum-forming character.[153] Ayers[154] has proposed to treat the gasoline with an adsorptive polymerization catalyst and subsequently add an aminobenzene. Complex condensation products, such as those formed from di-α-naphthylamine and cresol[155] or from a quinone, phenol or naphthol and an aryl amine, diamine or aminophenol,[156] or from an aliphatic ketone and a phenol,[157] are inhibitors. The reaction product of an olefin with a wood tar distillate boiling between 240-280°C. also has been employed.[158] An inhibitor may be added before or during the condensation of the fuel,[159] and more may be added subsequently. A color neutralizer may be incorporated simultaneously.[160]

EVALUATION OF INHIBITORS

Evaluation of the antioxidant effect of various inhibitors has been studied by Dryer and co-workers.[161] They recommended that antioxidant power be given as the "cyclohexene number," which is defined as the number of minutes that the induction period of pure cyclohexene, as determined in accelerated oxidation tests, will be retarded by 0.002 per cent of the substance under investigation. Instead of determining the cyclohexene number directly on the pure hydrocarbon, these investigators thought it better to use reference fuels. Gasolines from several sources were correlated with cyclohexene in respect to stability by using α-naphthol as an inhibitor. These were then blended with straight-run gasoline in such proportions that the final mixture required five times as much inhibitor to produce the same induction period as that exhibited by cyclohexene. Even when the quantity of added inhibitor was varied over a wide range, the correlation between the induction periods of these reference fuels and those exhibited by cyclohexene was fairly constant. This is shown in Fig. 206.

Because the inhibitors investigated were not very soluble directly in gasoline, liquids were sought which could be used as solvents (thus aiding dissolution of the inhibitor in the fuel) and at the same time not influence the results. Benzene and Hexone (methyl isobutyl ketone) were chosen as they filled the requirements satisfactorily. Cyclohexene numbers which were determined by these workers are given in Table 189.

Lowry and his collaborators[162] have suggested that it is possible to determine the inhibiting power of a substance by measurement of its critical oxidation potential. This is defined, for phenols and amines, as "the potential of some oxidizing solution which will cause a certain small amount of the amine or phenol to become oxidized in 5 minutes when equivalent amounts of the sample and of the oxidizing agent are employed."[163] Lowry and his co-workers also found that there was maximum inhibiting action shown by substances which gave a critical oxidation potential of between 0.600 and 0.800 volt. Their data are shown graphically in Fig. 207.

Dryer and collaborators[164] have investigated the storage stability of cracked gasoline as related to its induction period and the critical oxidation potential of added inhibitors. They used equimolecular amounts of various inhibitors. Part of the data they obtained is given in Table 190.

MECHANISM OF GUM FORMATION

It is well known that peroxides are intermediates in gum formation. Aldehydes and acids are also formed but they are present only as secondary products, according to Dryer and co-workers.[165] These investigators studied gasoline from several sources and concluded that the addition of inhibitors checked not only the development of gum, but also of peroxides, aldehydes and acids as well.[166] The results indicated that in all probability these oxygenated bodies are derived from the same source. The influence of various factors, such as the presence of different types of unsaturated substances and the effect of ultraviolet light, on peroxide and gum formation has been widely discussed.[167] Aromatic hydrocarbons with unsaturated side chains yield peroxides and are oxidized readily. However, Candea and Cristodulo[168] found that the high aromatic content of motor fuels derived from Rumanian

crude oils prevented any considerable peroxide formation. With a gasoline from Moreni crude oil, they observed[169] that cyclohexane and pinene promoted peroxide formation although the aromatic hydrocarbons present were not readily oxidized. Pipik and Mezhebovskaya[170] studied the influence of refining methods on the storage stability of gasoline. They noted that peroxides could be removed by treating the vapors of the fuel with floridin earth, and further formation prevented by the addition of an inhibitor immediately after refining.

Morrell and his collaborators have confirmed the belief that diolefins and olefins are essential for peroxidation.[171] They also showed that a mixture of olefins had a greater tendency to form gum than any of its components separately. The degree of oxidizability of various hydrocarbons (or mixtures of these) was measured by the peroxide number and gum content (air-jet method) before and after oxidation for 4 hours at 100°C. and 100 pounds pressure. In addition the induction period was also determined. Some of the data obtained in this manner are given in Table 191.

[171] J. C. Morrell, C. G. Dryer, C. D. Lowry, Jr., and G. Egloff, *Ind. Eng. Chem.*, 1934, **26**, 655; *Chem. Abs.*, 1934, **28**, 5648; *Brit. Chem. Abs.* **B**, 1934, 707; *J. Inst. Pet. Tech.*, 1934, **20**, 450A.

Peroxide number is defined, according to Yule and Wilson,[172] as the gram equivalents of active oxygen per 1000 liters of sample. This is estimated by determining the quantity of ferrous sulphate, dissolved in aqueous acetone, oxidized by 10 cc. of the sample under investigation.[173]

As a result of their studies on the effect of peroxide formation on a cracked gasoline, Morrell and his co-workers[174] found that an increase in peroxide concentration resulted in an increase in color and gum formation and a decrease in antiknock value and susceptibility to inhibitors. They also noted that the rate of peroxide formation and response to inhibitors were closely related.

Vellinger and Radulesco[175] report that the rate of gum formation in cracked gasoline is accelerated on exposure of the liquids (in quartz tubes) to ultraviolet light. However, they believed that oxygen was necessary for the development of gum, whether or not the latter occurred in the light or in the dark. It was observed that the hydrocarbons responsible for gumming were destroyed by chromic acid. Aside from olefins which form peroxides, the acetylenic hydrocarbons (which are either liquids or have been melted) also form peroxides.[176] Although this may be due to polymerization of the acetylenes to olefins which can then react with oxygen, it seems more probable that the acetylenes form peroxides directly. The alkyl acetylenes react more readily than the aryl derivatives, but acetylene itself does not seem to form a peroxide.

Morrell, Benedict and Egloff investigated the effect of light on gasoline[177] and on pure hydrocarbons.[178] In order to ascertain the effect of various conditions on the stability of the gasoline to color and gum formation, experiments were carried out on straight-run and cracked gasoline as well as a blend of these two. Elemental sulphur, *n*-propyl disulphide and both of these substances were added to different samples and the latter exposed to a carbon-arc light for 60 minutes while different gases, such as nitrogen, hydrogen, oxygen and carbon dioxide, were bubbled through the samples. In this way it was possible to get a large number of different conditions ranging from a sample with no added sulphur compounds in an inert atmosphere (such as nitrogen or carbon dioxide) to one containing sulphur and *n*-propyl disulphide in an atmosphere of oxygen. Part of the data which were obtained for gasolines are shown in Table 192.

It was observed that unsaturated hydrocarbons behaved similarly to cracked gasoline, and that in general the results for gasolines were the summation of the results for the constituent pure hydrocarbons. The presence of elementary sulphur or organic disulphides apparently makes for color instability. The haze formed in gasoline by the oxidation of sulphur was found to contain most of the acid. Gum formed, even in the absence of oxygen, but there was no fixed relationship between gum and color.

The amount of *n*-propyl disulphide used corresponded to 0.10 per cent sulphur.

COLOR STABILITY OF PETROLEUM DISTILLATES

Hillman[179] has classified the types of color instability of kerosene:

1. Clear lemon-yellow which appears in the dark and is an oxidation effect due to various types of compounds, especially unsaturated naphthenic acids.
2. A similar type due to amino-bodies.
3. Discoloration caused by cracked bodies.
4. A gradual brownish coloration due to age and light.

An indication of the color stability is given by the Hillman test which consists of agitating 700 cc. of kerosene for 60 seconds with 1 g. of standard lead dioxide moistened by 20 ml. of 0.175*N* caustic soda. The kerosene is filtered before and after treatment to remove suspended matter. A positive test, i.e., an increase in color, shows definite color instability of the sample, but a negative result is inconclusive. Moerbeek[180] has pointed out the desirability of using lead dioxide of standard activity. Because of the difficulty in obtaining a standard product and storing it, he recommended that lead dioxide be obtained from one source to insure at least its original uniformity. He suggested the use of the silicotungstic acid test for nitrogenous substances which might cause color instability. Van Senden[181] has proposed a somewhat different procedure in which alkaline potassium ferricyanide is used in place of alkaline lead dioxide. He found that color stability was influenced by methods of refining and storage during shipment, such as copper valves in the bottoms of tanks. The discoloration of Borneo and Rumanian gasolines is believed to be due not to nitrogenous substances but more probably to phenolic compounds or substances similar to cyclopentadiene.[182]

Lowry, Smith and Murphy[183] have developed a standardized test for color stability of gasolines. Using a commercial flame-type carbon arc as a light source (in a specially designed housing), these workers measured the change in color of various gasolines with time of exposure. Reproducible results in routine work are reported. The color instability of kerosene in storage under tropical conditions was investigated by Allibone.[184] He found that extraction with sulphur dioxide (Edeleanu process) followed by filtration through bauxite gave a product of low tint and satisfactory stability. Extraction of fuels by aqueous glycol while exposed to actinic light rays is reported to remove chromophoric substances.[185] Brooks[186] suggested the use of ammonia as a color stabilizer. Sorg[187] has investigated the power of various primary aliphatic amines, containing primary, secondary and tertiary alkyl groups, to prevent discoloration of gasoline. (See Fig. 208.) The results showed amylamine was the most satisfactory at a concentration of about 0.003 per cent. No loss of stabilizing power was observed when the amines were added to sour distillates and the latter subjected to sweetening with sodium plumbite and sulphur. The addition of a solution of pyrogallol in ethyl or isopropyl alcohol was found not only to restore the color of stored distillates but also to stabilize them satisfactorily for 6 months.[188]

FIG. 208.—Comparison of Amines as Color Stabilizers for Gasoline. (L. V. Sorg)

Many compounds which are applicable as gum inhibitors also prevent discoloration, examples of such being: urea,[189] resorcinol, pyrogallol, hydroquinone, catechol, naphthols,[190] quinhydrone[191] and cyclic organic acids such as salicylic and anthranilic,[192] primary aromatic amines,[193] unrefined corn oil[194] and aliphatic-amine salts of hydroxy-aryl compounds, e.g., hydroquinone dianilide.[195] It has been found advantageous to use polyhydroxybenzenes as color stabilizers in the presence of various gum inhibitors such as α-naphthol, α-naphthylamine or *p*-phenylenediamine[196] or an alkyl amine[197] or an anthracene or phenanthrene hydrocarbon in the presence of an α-substituted naphthalene derivative,[198] or sodium thiosulphate in the water layer (if the latter is used in storing).[199] N-Alkylated monoethanolamine has been suggested to prevent the formation of color in gasoline to which aromatic amines have been added as antioxidants.[200] Hydroxyalkylamine esters[201] and phenolates[202] have been recommended.

In many cases, refining processes increase the color-stability of gasolines. For example, crude cracked gasoline may be treated with alcoholic ferric chloride before or during distillation.[203] Benedict and Wirth recommend the use at not higher than 93°C. of sulphuric acid containing ferric chloride,[204] or hydrochloric acid containing ferric sulphate.[205]

Elimination of Gum-Forming Constituents by Refining

It has been shown earlier in this chapter that the formation of gum and color in gasoline is dependent upon oxidation phenomena and may be inhibited by the addition of various substances. The latter act as antioxidants, and, during their periods of activity, prevent oxidation of unstable substances present in the gasoline. In order to conserve inhibitors occurring naturally in unrefined gasoline, Vellinger and Radulesco[206] have suggested that the unrefined distillate be distilled to give two fractions the boiling ranges of which must be determined for each fuel. The high-boiling fraction is given a mild refining treatment with clay because it contains most of the natural inhibitors. On the other hand the lighter fraction can be refined by the usual methods and then be blended with the other fraction.

Although methods of refining are beyond the scope of this book, nevertheless procedures developed primarily for the removal of unsaturated hydrocarbons which tend to yield gum are of interest and these are briefly described. They may be classified under the following general headings:

1. Clay treatment of the gasoline in either liquid or vapor phase.
2. Treatment with acids, such as sulphuric, phosphoric or hydrochloric.
3. Treatment with inorganic polymerization agents, e.g., zinc or aluminum chloride.
4. The use of alkali or alkaline earth metals and derivatives.
5. Various other reagents and treatments.

Vapor or liquid phase treatment with clay has met with some favor. Operations may be carried out using clay[207] alone or in conjunction with various substances which will effect polymerization of unsaturates. Day has described a process in which gasoline is treated with aqueous hydrogen chloride in the presence of a natural zinc-bearing clay.[208] A "gumbrin" clay also has been recommended.[209] In some cases an organic inhibitor may be added after the clay treatment.[210] Fuller's earth may form part of the bed upon which another more active inorganic substance, such as ferric sulphate, is distributed.[211]

Kwal[212] has suggested the use of "Carbonit" earth and hydrogen peroxide in refining lignite spirits.

Refining may be effected in the vapor phase with a gaseous acid anhydride and steam[213] or in either the liquid or vapor phase with sulphuric[214] or phosphoric[215] acid. Treatment of distillates with hydrogen chloride, or solutions of it, in the presence of metals aids in the removal of gum-forming constituents.[216]

Inorganic polymerization agents have been employed in some of the above mentioned processes in the presence of acids, particularly hydrochloric. The use of solutions of hydrochloric acid and the chlorides of iron,[217] zinc[218] or copper,[219] or mercury[220] and solid metal oxides, as of zinc or tin at about 120°C.[221] or below a cracking temperature,[222] are examples.

Treating gasoline with zinc chloride[223] polymerizes many of the gum-forming olefins present so that the stabilized gasoline may be distilled from the polymers. Other inorganic salts used similarly are aluminum chloride[224] and salts of copper,[225] iron[226] or cadmium.[227] Brückner and Lang[228] found that treatment of cracked benzine with ferric chloride results in less loss than with acid followed by alkali washing. This chloride also compared favorably with aluminum or zinc chloride as a refining agent. The addition compounds formed from aluminum chloride and olefins[229] or aluminum chloride and phenols may be used as treating agents.[230]

Operations involving the use of alkali metals have been proposed.[231] Amalgams of alkali metals,[232] the hydrides of alkaline earth or alkali metals,[233] alkali metal permanganates[234] and alkali metal pyrosulphates or persulphates with sulphuric acid[235] have been suggested for removing the gum-forming constituents of gasoline.

Other methods[236] of treating include: heating with sulphur monochloride,[237] heating,[238] hydrogenation,[239] treatment of a fraction and re-mixing,[240] treatment with copper silicate[241] followed by the addition of organic inhibitors,[242] and extraction with aqueous solutions of glycol[243] or furfural.[244] Both aryl and aliphatic sulphonic acids have been added to gasoline to resinify the polyolefins present.[245] Organic compounds containing the grouping represented by =CH—CO—, such as maleic anhydride,[246] and pyridine or hydroquinone and air in the presence of a metallic oil-soluble soap (copper naphthenate)[247] are recommended for removing gum-forming constituents from gasoline.

AUTOXIDATION OF LUBRICATING OILS

Fachini and Sporer[248] have classified lubricating oils into four groups:

1. Those which are unstable and sludge rapidly.
2. Those which sludge slowly at first, but afterwards more rapidly.
3. Those which sludge rapidly at first, but subsequently oxidize slowly.
4. Those which are very stable over long periods.

They aged lubricating oils artificially[249] by heating in a porcelain crucible (with specified dimensions) at 150°C. for various times. The presence of a gasoline-insoluble residue after 15, 75 or 100 hours placed the oil in Group 1, 2 or 3, respectively. Oils in which no sludge formed, even after 150 hours, were placed in Group 4.[250] According to some investigators, sludge is caused by the development of asphaltenes, and "carbon" formed by oxidation depends on the engine conditions.[251]

Gruse[252] has outlined the possible sources of coke or carbon formation as:

1. Slow oxidation of crankcase oil to resins and asphaltenes.
2. Low-temperature coking of these products in piston-ring grooves and on the piston.

3. Rapid cracking of these products (and any originally present in the oil) and of unvolatilized oil on the surfaces of the combustion chamber.

Because of these three possible sources of carbon, there are three types of test which may be used in evaluating the tendency of a fuel to carbonize. These are oxidation, distillation and coking tests. Gruse believed that none of these was wholly satisfactory because oxidation tests had not established any significance for ordinary service, distillation tests did not take into account dissolved resins and coking tests did not allow for the presence of substances of excessively high boiling point.[253] Bassett[254] has suggested that coking may be ameliorated by proper choice of fuel and lubricant, filtration of air supply and the addition of an antioxidant to the lubricant.

Evers and Schmidt[255] have proposed that the aging of oils be carried out by an oxidation process. The ratio of actual increase to calculated increase in saponification number (the latter based on the amount of oxygen absorbed) is about 1 :3 for oils. This is said to show the formation of oxygen compounds other than acids or esters. These investigators proposed that the rate of absorption of oxygen by an oil be determined under specified conditions and be used as an index of the oxidizability of the oil. They recommended absorbing the oil on silica gel impregnated with cupric oxide and oxidizing it with pure oxygen at 100°C. and atmospheric pressure. The rate of absorption was followed by measuring the current necessary to form enough oxygen by electrolysis so that the pressure in the reaction chamber remained constant. The whole operation is carried out in a specially designed apparatus and is reported to be quick and accurate, and the results are said to be reproducible.

Using the method of Evers and Schmidt, Lederer[256] has studied the rate of oxidation of hydrocarbons, alcohols, phenols, aldehydes, fatty acids and benzene. He found that there was evidence of peroxide formation in the oxidation of compounds containing not less than two double bonds and an active group such as hydroxyl or carboxyl. He reported that the "oxidation number"[257] is generally sufficient to give insight into the oxidation characteristics of lubricating and transformer oils. Chernozhukov[258] investigated the oxidizability of several Russian and other lubricating oils. He employed the Butkov[259] method for the oxidation at 150°C. and 15 atmospheres of oxygen.

Evans studied the oxidation of lubricating oils by heating in a sealed glass tube, rotated so that a new film of oil would always be exposed.[260] He stated that at certain temperatures the oil molecule is broken down into substances which tend to cause sticking of the piston-rings and carbonization.[261] The oxidation-stability of oil for use in aeroplane engines was found to be of greater importance than its oiliness. Oxidation was catalyzed by various metallic substances. The composition of the sediment is the same whether formed in laboratory or in an engine, but a highly oxidized form is found in the hotter portions of the motor.[262]

Garner and his co-workers[263] have studied the influence of various factors, such as contaminations and temperature variations, on the results obtained in the British Air Ministry test. This test consists of the passage of 15 liters of air an hour through a 40 cc. sample of oil maintained at 200°C. for 2 periods of 6 hours each on consecutive days. After this treatment, the stability of the oil is determined by the changes produced in the coke number and the viscosity. Auld[264] has suggested that the test may be made a little more discriminating by raising the temperature to 250°C. Comparison of the British test with that of the French Air Ministry has shown similarity of results with these two methods.[265] Although the absolute values of six various types of oils differed with the test employed, there was the same order of classification in each case. The fact that the British and French tests employ different methods (the former carried out at 200°C. without a catalyst and the latter at 140°C. with a catalyst), and yet classify lubricating oils in the same order, was taken to confirm the view that deterioration takes place by oxidation and polymerization and that a catalyst such as copper accelerates but does not change the nature of the reaction.

Heating lubricating oils at 130°C. for 50 hours in the presence of air and of copper has been suggested as an aging test by Dackweiler.[266] The results parallel those for the measurement of ether-insoluble asphalts. Chernozhukov and Krein[267] have studied the oxidation of lubricating oils containing naphthenes and aryl and hydroaryl hydrocarbons. They found that a lubricating oil composed of naphthenes and 15 to 20 per cent aromatic hydrocarbons increased in acidity on oxidation but formed no precipitate. The course of the reaction followed was that which it would have taken in the absence of naphthenes. However, in the presence of 10 per cent or less of aromatics, the oxidation followed the course for straight naphthenes. They also observed that if there was 5 per cent of hydroaryl hydrocarbons in a naphthenic oil, a precipitate was formed on oxidation which consisted of hydroxy-acids, asphaltenes and carbenes. At higher concentrations the hydroxy-acids are the predominant products. The asphaltenes were thought to originate from the aralkyl hydrocarbons, such as diphenylmethane and its homologues, which may occur in the oil.

In Diesel engines, aging of lubricating oils is said to consist in an oxidation which takes place on the cylinder walls, resulting in the formation of asphaltic products. The latter are insoluble in the oil but soluble in chloroform.[267a] Further aging leads to products insoluble even in chloroform.

Dornte and Ferguson[268] investigated the oxidation of oils whose oxidation is unaffected by the non-volatile products formed. They showed that the total oxygen absorbed was a linear function of the time at constant oxygen pressure and constant temperature. Water and carbon dioxide, with some carbon monoxide, were the only products of oxidation. The absence of peroxides was believed to be characteristic of this type of reaction. The catalytic powers of copper, iron, lead and tin were studied. Copper had a rather pronounced effect, while the others exerted little if any influence. The metal to oil ratio and partial pressure of the oxygen affected the catalytic power, especially of copper. Similar work subsequently was undertaken with that type of lubricating oil whose rate of oxygen absorption continuously decreases, probably due to a decreasing concentration of the reacting components of the oil.[269] From the oxygen absorption data, an empirical equation was obtained:

$$V^2 = kt$$

where V = total volume of oxygen absorbed in cc. at standard conditions per 100 grams of oil,
t = time in hours,
and k = rate constant obtained by plotting V^2 against t.

This equation indicates that the reaction probably was retarded by the oxidation products. However, the rate of reaction varied linearly with the partial pressure of the oxygen. In addition to the oxidation products of the first type of oil,[270] acids were detected and similar catalytic effects of metals were noted. Below 250°C. tin and some of its compounds act as antioxidants for lubricating oils.[271] The extent of this effect depends upon the specific compound, the type of oil, concentration in the oil and other conditions of the test. Soluble fatty acid salts, naphthenates, phenolates and such organo-metallic derivatives as tin tetraphenyl were found to be oxidation inhibitors. It was suggested that the tin compounds might have reacted with an auto-catalyst formed during oxidation. Tin tetraethyl and tin ricinoleate may be used in amounts up to 1 per cent.[272]

Various investigators have suggested tests to ascertain the stability of oils to oxidation.[273] Guthrie and co-workers[274] have proposed a "stability number" which is said to be useful in conjunction with results obtained in service. The procedure is to oxidize 150 cc. of oil for 5 hours at 388.8°F. by passing 2.2 liters of oxygen through it per hour. The changes produced in kinematic viscosity, carbon residue, precipitation number and neutralization number are determined. The "stability number" is then one-fourth of the sum of 4 times the change in viscosity, plus 100 times the change in carbon residue and 100 times the changes in both the precipitation number and neutralization number.

Rogers and Shoemaker[275] have described the widely used Indiana Oxidation test. This is carried out in oil test tubes, 40 to 44 mm. inside diameter and 450 to 500 mm. in length, and placed in an oil bath heated to approximately 342°F. The apparatus is shown in Fig. 200. The temperature can be regulated closely by means of electric heating units. Air is blown through the oil samples at a predetermined rate. At intervals samples are taken and asphalts determined by precipitation with naphtha. The times required for the formation of 10 and 100 mg. of asphaltene per 10 g. of oil are determined as indexes of the oxidizability of the oil. Details of the procedure are:

> "Fill the oil tube to a depth of 23 cm. (approximately 300 cc. of oil). Place the tube in the bath, the level of which must be at least 5 cm. above that of the test oil. The oil bath must be up to temperature and so maintained that the temperature of the

test oil is 341 ± 0.5°F. The air delivery tube is placed so that the end is within 6 mm. of the bottom of the oil tube. One-half hour after placing the oil in the bath, start the air at a rate of 10 ± 1 liters per hour (as measured under laboratory conditions). The start of the test period is the time of starting the air.

"For determination of the sludge values withdraw a 25-cc. sample of the test oil in a pipet. Weigh 10 grams (± 0.1 g.) of this portion immediately into a 300-cc. Erlenmeyer flask, and dilute with 100 cc. of A.S.T.M. precipitation naphtha.[78] The naphtha used must, by comparative test on a sample of oxidized oil, give within 25 per cent of the sludge value obtained with a reference sample of A.S.T.M. precipitation naphtha. Stopper the flask and allow the solution to stand for 3 to 3.5 hours at room temperature (70 to 85°F., 21.1 to 29.4°C.).

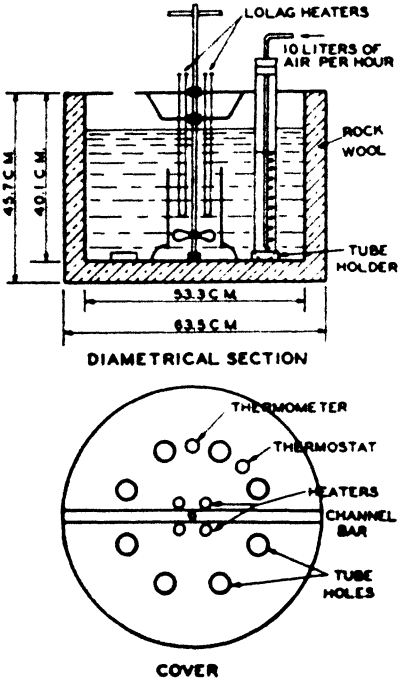

FIG. 209.
Drawing of Apparatus for Indiana Oxidation Test. (T. H. Rogers and B. H. Shoemaker)

Courtesy Industrial and Engineering Chemistry

"Prepare a Gooch type crucible (approximately 35 mm. in diameter) with a mat of 0.5 to 0.65 g. of medium asbestos fiber. During preparation of the mat, press it down before adding the last portion. Dry the crucible at approximately 300°F. (148.9°C.) for at least 2 hours in an oven and weigh. Filter the sample, wash with precipitation naphtha, heat at approximately 300°F. for 0.5 hour and weigh. Express the sludge as milligrams per 10 g. of oil."

"Samples for sludge determinations may be taken every 24 hours before sludging begins. Take at least three samples giving sludge values between 5 and 125 mg., including one between 5 and 20 and one between 50 and 125. A plot of these values *vs.* time on log paper is then used to determine the sludging time and the 100 mg. time. For tests made at barometric pressures differing by more than 5 per cent from 1 atmosphere, correct these times to normal barometric pressure by multiplying the observed time by the ratio of the barometric pressure during the test to 760.

"For determination of viscosity increase, samples of approximately 75 cc. are withdrawn every 50 hours and used to run Saybolt viscosity. This oil is then replaced in the test tube."

This test is said to be reproducible within 10 per cent by different operators.

Fairlie[277] has designed an apparatus in which oil may be aged to give results comparable to actual use in a motor. The apparatus consists of a sump from which oil is pumped into a header-tank. From this it flows to an aerator and then through a heating coil 40 feet long. It passes from the heater to a cooler in which the cooling water runs at a rather high temperature (at boiling if room temperature is above 80°F.). The essential conditions are: 4 liters of oil in sump, 220°F. sump temperature, 300 ml. per hour flow through heater and a heater outlet temperature of 425°F. Tests are run for 150 hours, samples being taken at the end of 50, 100 and 125 hours and inspected for the proportion of sediment or sludge formed.

The experimental study of the oxidation of lubricating and heavier oils has shown, according to Obenaus,[278] that reliance upon the results of only one test, such as carbon residue, acid number or viscosity, may give erroneous conclusions as to the aging properties of the sample. According to Nikiforov and his collaborators, oxidation of motor oils by various methods showed that the main change was cracking due to the action of metals at high temperatures on the oil.[279]

By treating transformer oil sludge with dilute aqueous nitric acid and ether, Boisselet and Mouratoff[280] found that the oxidation products included acids and metallic soaps. Extraction of either used or aged motor oil with sodium hydroxide has given various oxy-acids.[281] The extraction of an alkali-treated oil with gasoline removes resinous material[282] and hence influences the tar number as determined by the Kissling test.[283]

Water vapor has so pronounced an influence on asphalt formation that even the humidity of the laboratory may affect the amount precipitated from aged mineral oils by benzine.[284] Organic substances, such as acetone and alcohol, also increase the amount of precipitate. Consequently precipitations should be carried out in tight containers where contaminants can not be introduced, and the solutions should settle in the dark. Weiss and Vellinger[285] have studied the oxidation of oil and found that increased water vapor decreased the amount of deposit and increased the volatile acids formed as shown in Fig. 210. They considered that the study of several properties, such as sludge formation, fixed and volatile acidity, interfacial tension, and color during artificial aging of any class of oil, showed more in regard to the properties of that oil than the volume of oxygen absorbed.

Investigations have shown that oiliness decreases quite rapidly by oxidation at 75°C.[286] Substances such as β-naphthol act as inhibitors for the reaction and simultaneously improve the lubricating properties of the oil to a certain extent. King[287] has investigated the behavior of oils under relatively high temperatures (200 to 300°C.) and found that oils which normally maintain a film up to 160°C.

could lubricate up to 300°C. because of what he termed "oxidation lubrication." This was observed, for example, in the case of a blend of 40 per cent "bright stock" and 30 per cent each of a paraffin and asphaltic base distillate.

OXIDATION OF WHITE OILS

The oxidation of white oils is a rather special example of the oxidation of lubricating oils which are prepared by drastic refining. Dornte[288] reported that the oxidation of white oil is an autocatalytic process involving a chain mechanism. He deduced an empirical equation to represent the results of his experiment:

$$V^{\frac{1}{2}} = kt + n$$

in which V is the volume of oxygen absorbed in cubic centimeters reduced to standard conditions per 100 g. of oil, k is the constant which characterizes the rate of oxidation reaction, t is the time in hours and n is considered a function of inhibition due to natural inhibitors present. It is negative when an inhibitor such as phenyl-α-naphthylamine has been added. Experiments were conducted by the absorption of oxygen at 115 to 145°C.

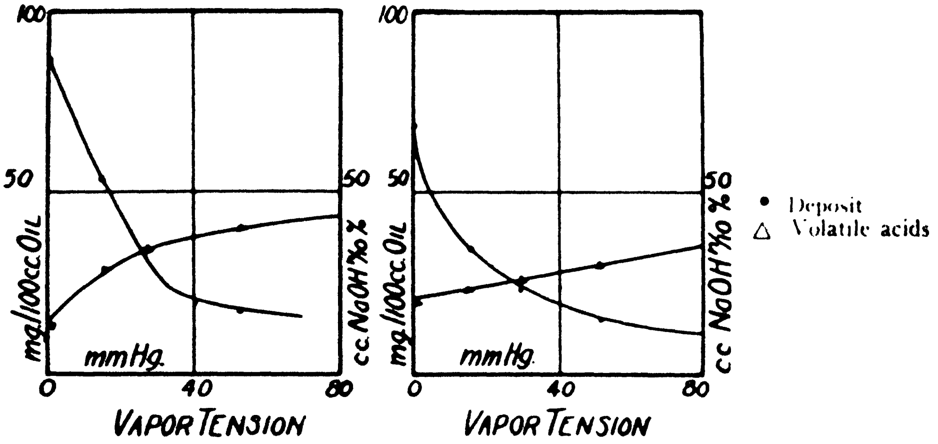

FIG. 210.—Influence of Air Humidity on Oxidation Products from Two Oils. (H. Weiss and E. Vellinger)

The oxidation of synthetic mixtures of naphthenic hydrocarbons (pure medicinal white oils) and aromatic hydrocarbons by the method of Butkov[289] has shown that aromatic compounds in general are more readily oxidized than naphthenic hydrocarbons, although the latter seem to induce the reaction.[290] The antioxidant properties of aromatic substances are improved by the presence of a trivalent carbon or an increase in the number of rings. Inhibitors of the oxidation of naphthenes are phenols, quinones and resins of aromatic origin, although they affect the appearance of the oils.[291] On the other hand, aldehydes, ketones, acids, hydroxy acids and phenol acids reduce their stability.

[290] N. I. Chernozhukov and S. E. Krein, *Neft. Khoz.*, 1933, **25**, 35, 102; *Chem. Abs.*, 1934, **28**, 621.

Yamada[292] has observed that a greater proportion of acidic substances is formed in the oxidation of white oil in the absence of dehydrating agents, such as phosphorus pentoxide or potassium hydroxide, than in their presence. This is analogous to the results reported by Weiss and Vellinger[293] on the action of water. Alcohols were found to be primary oxidation products although they were not active centers for subsequent oxidation.

The stabilization of white oils is effected in the same way as in the case of other petroleum products, viz., by the addition of antioxidants. Alkene diamines of the types $H_2N\text{-}CHR\text{-}CHR'\text{-}NH_2$ and $(CH_2)_n(NH_2)_2$ or their derivatives,[294] oil soluble mercaptans containing more than 7 carbon atoms,[295] and aromatic mercaptans or disulphides or the corresponding selenium or tellurium compounds[296] are useful as antioxidants for refined petroleum oils. Archibald[297] has noted that refining of mineral oil to give a product to conform to the U. S. Pharmacopoeia removes some substances which are antioxidants. He has suggested ether-extraction of the clay used in filtering the oil, distilling off the solvent and adding small amounts (0.02 to 1.0 per cent) of the residual oil to the final product to protect the latter against oxidation. The methyl alcohol-extract of spindle oil may be blended with a highly refined white oil to give an insulating oil.[298]

OXIDATION INHIBITORS FOR LUBRICATING OILS

The formation of sludge by the autoxidation of lubricating oils has been investigated by Tanaka, Kobayashi and Furihata.[299] They reported that substances which acted as antioxidants under certain conditions might be pro-oxidants in oils with other characteristics. They proposed an explanation based on the formation of a peroxide of the autoxidizable substance, A, which can react with the added substance, B:

$$A\,O_2 + B \underset{K_2}{\overset{K_1}{\rightleftharpoons}} B\,O_2 + A$$

where K_1 and K_2 are the reaction-velocity constants in the directions indicated. The higher the ratio of K_1 to K_2, the more effective B is as an antioxidant

The autoxidation of lubricating oils in storage may be hindered by methods similar to those used for gasolines and white oils. White lubricating oils may be blended with pale lubricating oils to stabilize the latter[300] against sludge formation. Shoemaker[301] has suggested the addition of an oil-soluble amide such as dibutyl sodamide. The naphthenates of various metals, such as manganese, lead, zinc, copper, aluminum, cobalt or calcium, are stabilizers for lubricating and transformer oils.[302] Tin compounds, such as tin oleate and tin tetraphenyl, are reported to inhibit the deterioration of oils,[303] whereas compounds of copper, iron, silver, vanadium and manganese are said to accelerate the rate of deterioration. Compounds of gold, mercury, chromium, cerium, bismuth and antimony have little influence. Tin compounds may be added with lead compounds, the latter intended to raise the spontaneous ignition temperature.[304] Chromium oleate is reported to inhibit oxidation and minimize the corrosion of metal surfaces.[305] Organic compounds of tin or lead may be added together with an oil-soluble organic compound of chromium.[306] Organic derivatives of elements of Groups II, III or V of the Periodic Table may be added to lubricating oils.[307] Examples are trinaphthyl-α-propyl bismuthine, cadmium dicresyl, triphenyl bismuth and di-tolyl mercury. They are said to be effective at 200-250°C. Aromatic disulphides and mercaptans and the corresponding selenium and tellurium compounds are reported to be inhibitors in oils, other than white oils, which have a high rate of oxidation.[308] Hydroxy- and amino-diaryl ethers or sulphides have been suggested as antioxidants.[309]

The mechanism of the oxidation of transformer oils is very similar to that for lubricating oils.[310] Vellinger and Müller[311] have investigated the oxidation of mineral oils by atmospheric oxygen at temperatures between 100 and 150°C. In the accompanying graphs, Fig. 211, the effect of addition of copper stearate in amounts of 2 to 25 mg. to 100 cc. of oil is shown.

In experiments in which copper stearate was added directly to the oil, curves such as *A* were obtained. Curve A_1 represents a mixture containing 25 mg. copper stearate per 100 cc. of oil, A_2 containing 10 mg., A_3 5 mg., and A_4 2 mg. However, it will be noticed that in curve *B* the initial period (from its origin to point *T*) influences the rate of asphalt formation. During this period copper was being dissolved from small, polished copper cubes placed in the oil. After the time *T*, even removing the cubes entirely had no effect because they had become inactivated by adsorption of some substance present in the oil and did not dissolve any further. When the oil was initially acid either from an added organic acid or from heating in the absence of a metal, copper dissolved very readily and a curve such as *C* was obtained.

From these results Vellinger and Müller concluded that the rate of formation of sludge in a transformer oil depends upon the amount of dissolved copper. The area of copper exposed to the oil had an influence on the amount of asphalt formed (Curve *D*) because of the greater amount of copper dissolved from a large surface. Curve *E* shows the effect of copper stearate on the reaction velocity of the oxidation.

Müller, *Compt. rend.*, 1935, **200**, 1769; *Brit. Chem. Abs.* **B**, 1935, 709. Müller has studied the oxidation of transformer oil on prolonged heating. He found no relation between the volume of oxygen absorbed and the formation of deposit.

Gemant[312] has measured the absorption of air by mineral oil at 20 and 80°C. He concluded from his data that the absorption is not purely physical but is accompanied by a reversible oxidation. It has been observed that the oxidation of transformer oil is a monomolecular reaction in which the reaction constants and energy of activation vary because of the presence of different hydrocarbons.[313] It was also reported that activation energy increased with the time of oxidation because of the disappearance of readily oxidizable material and not because of autocatalysis. Oxidation of over-refined oils gave products which remained in solution, although the reverse occurred with under-refined oils.

FIG. 211.—Effect of Copper Stearate on Rate of Asphalt Formation in Air Oxidation of Mineral Oils. (E. Vellinger and G. Muller)

Thin films of tin, lead and copper have a catalytic effect on the formation of sludge in insulating oils, which increases in the order named. The effect of tin, however, is slight, and it may even be an anti-oxidant.[314] Copper catalyzes the oxidation of naphthenes to asphaltogens more readily than iron, although the activity is reversed in the oxidation of aromatic hydrocarbons to phenols.[315] Kurlin and Blinova,[316] among others, have observed that severe refining decreases the stability of oils. Over-refined oils have been used in transformers in order that the inert gas formed by their decomposition may remain above the oil and reduce explosion hazards.[317] Contrary to beliefs once held, the addition of fresh oil to a transformer does not increase the rate of sludge formation unless, in some cases, the original oil was of inferior quality or excessively aged.[318]

The effect of circuit-breaking and high temperatures on a transformer oil has been studied,[319] and it was found that the amount of gas formed increased rather rapidly with the number of breaks and came out of solution readily.

One of the most important properties desired in a transformer oil is resistance to that oxidation[320] which results in the formation of sludge and acid.[321] This is a sequence of unimolecular reactions of the different oils present. Weiss and Salomon[322] have used the time required for the production of a trace of deposit in oil heated at 114-117°C. in contact with air as an index of alterability. They classified oils which formed deposits in less than 10 hours as very alterable. Those yielding deposits of more or less than 0.008 g. (per 100 cc.) in 15 to 24 hours were considered to be of average and slight alterability, respectively. If the time required for deposition was longer than 36 hours the oil was very slightly alterable. Gemant[323] described a rapid measurement of the oxidation of insulating oils in air. In his method, a sample of oil is kept in a closed space at 145 or 155°C. under a constant pressure. The progress of the oxidation can be followed by measuring the decreasing volume of air above the oil.

The deterioration of steam-turbine oils[324] may be measured in a manner similar to that used for transformer oils.[325]

Chebotar[326] has observed that the Sligh and Michie tests measure only the sludge formed by the oxidation of transformer oil and do not take into account the formation of acids. He determined oxidizability by heating the sample in a bomb with oxygen at 151°C. and 300 pounds pressure and noting the pressure drop. The naphthols, naphthylamines and diphenylamines inhibited the oxidation of "Nujol" (a white medicinal oil), but not of transformer oil. On the contrary β-naphthylamine even accelerated the oxidation of the latter oil. Phenyl-α-naphthylamine is not as satisfactory in practice as in the laboratory, according to Typke.[327]

The oxidation of solar oil by air under pressure is catalyzed by the addition of various metal naphthenates. The rate of oxidation is proportional to the pressure and is greater for more highly refined oils.[328]

Chapter 41

Oxidation of Aromatic Hydrocarbons

Since aromatic hydrocarbons can be isolated from petroleum fractions in some degree of purity by the sulphur dioxide extraction process[1] and by other methods, the oxidation of these compounds is of considerable interest to petroleum chemistry. By careful separation of that fraction of an Oklahoma crude boiling between 107 and 108°C., as much as 32 per cent toluene was recovered.[2]

Various catalysts have been used in the partial oxidation of the aromatics; in general, the oxides of vanadium, tungsten and chromium have been found best suited to the operation. Charlot[3] reported an investigation of the oxides of boron, beryllium, magnesium, aluminum, silicon, titanium, vanadium, chromium, manganese, iron, nickel, cobalt, cadmium, copper, lead, zinc, zirconium, columbium, molybdenum, tin, antimony, tellurium, tantalum, tungsten, thorium, bismuth, thallium, uranium, lanthanum, cerium, praesodymium, neodymium, and samarium. A number of combinations of two or more oxides were investigated, as well as the metallic catalysts such as nickel, copper, lead, cobalt, platinum and palladium. The metals are approximately 50 to 100 times as active for complete oxidation as are the difficultly reducible oxides, but these metals tend to promote destructive total oxidation by this excessive activity. The amount of substance undergoing partial oxidation is independent, over a considerable range, of the time of contact, the concentration, or the nature of the organic substance, according to this investigator. The catalyst employed is the deciding factor.

In the partial oxidation of benzene, Newitt and Burgoyne[4] report, there are only three stages before ring-rupture takes place. They believe that, in the case of benzene, oxidation under high pressure proceeds as a series of hydroxylations, yielding successively phenol, hydroquinone, and finally quinone. With toluene and ethylbenzene under high pressure, the side chain and the ring are oxidized simultaneously. (See page 943.)

A definite induction period occurs in the oxidation of toluene and ethylbenzene although there is none in the oxidation of benzene. On the other hand there is a surface effect[5] in the latter oxidation but none in the case of toluene and ethyl benzene. From these results the investigators concluded that there is a chain mechanism involved in each case, though the mode of propagation differs.

Stephens and Roduta[6] have studied the reactions of more complex alkyl-substituted benzenes, particularly tertiary hydrocarbons, and report that in these cases oxidation always occurs at the α-carbon atom (the side-chain carbon directly ad-

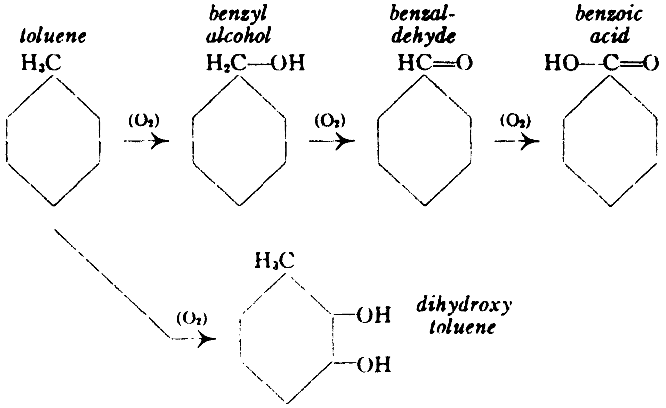
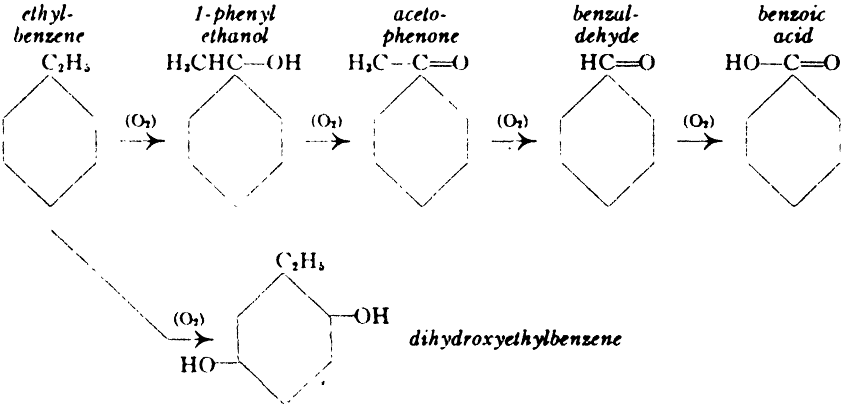
[5] In this instance, a greater surface-to-volume ratio retards the reaction. The effect of surface-volume ratios is more fully discussed in Chapter 36.

[6] H. N. Stephens and F. L. Roduta, *J.A.C.S.*, 1935, 57, 2380; *Chem. Abs.*, 1936, 30, 1750; *Brit. Chem. Abs.* A, 1936, 324.





jacent to the ring). With methylethylphenylmethane, methyl-*n*-propylphenylmethane or methyl-*n*-butylphenylmethane, oxidation proceeds to yield acetophenone almost exclusively; if there is any tendency to yield the higher phenones (propriophenone or butyrophenone) the relative yields are so slight the products could not be detected. Experiments with an example of a secondary hydrocarbon, diphenylmethane, showed that oxidation led to benzophenone provided no water was present, but the reaction was inhibited by the presence of water. It was suggested that this was due to reversible decomposition involving the loss of water. On the other hand, in the case of the tertiary hydrocarbons no inhibitory effect was observed either with respect to the previously mentioned tertiary hydrocarbons or to triphenylmethane or methyldiphenylmethane. This may find explanation in the fact that the formation of a molecule of water from a molecule of a primary addition product of oxygen and a tertiary hydrocarbon would require the contribution of one of the hydrogen atoms from an alkyl group. The resulting alkene residue then must drop off if a ketone, which is always the observed product, is formed. The loss of a carbon atom attendant upon the elimination of water may so reduce the probability of reversal of this step by excess of water that no observable inhibition occurs. Evidently, from these results the larger aliphatic group attached to the tertiary carbon tends to contribute the hydrogen and is thus eliminated. In the case of triphenylmethane, where no alkyl groups are available, the oxidation products are benzophenone and phenol.

An investigation of the slow oxidation of benzene in the vapor phase, using ethyl nitrate as a catalyst, has been reported by Griffith and Hill.[7] These investigators found that there was no appreciable induction period in the oxidation, but that the reaction time varied directly with the benzene-oxygen ratio and the pressure, and inversely with the absolute temperature and the concentration of ethyl nitrate catalyst. The surface effect was quite pronounced as the reaction velocity was considerably lowered by increasing the surface-volume ratio. Similarly, the addition of a small amount of tetraethyl lead counteracted the accelerating effect of the ethyl nitrate. In general, it was found that the reaction catalyzed by ethyl nitrate at 430 to 480°C. was similar to the uncatalyzed reaction at 530°C. If concentrations of ethyl nitrate exceeding 0.35 per cent are employed, the reaction becomes explosive, but short of the explosive reaction, the intermediate products are the same as those produced in the purely thermal reaction at a somewhat higher temperature.

However, in the oxidation of benzene and its derivatives and homologues, metallic oxide catalysts are generally employed. Pigulevskii and Yarzhemskaya[8] have studied this reaction and reported that benzene, oxidized in the presence of vanadium pentoxide (on fireclay) at 370 to 450°C., proceeds through benzoquinone to maleic anhydride and then to carbon dioxide and water. For maximum yields of maleic anhydride these investigators recommend high gas velocities through the reaction chamber and rapid cooling of the resultant gases. Under these conditions a yield of about 38 per cent of maleic acid was obtained. Three condensers in series were employed in collecting the reaction products; one air-cooled to room temperature, one cooled to 0°C. in ice water, and a final trap cooled in liquid air. Maleic acid was obtained under these conditions, but when the first (air-cooled) condenser was maintained at 40 to 50°C. to prevent condensation of water vapor, only pure anhydride was collected there. In addition to these principal products, over 4 per cent of quinone was formed and complex decomposition products probably containing quinhydrone. It is suggested that the reaction goes from benzene through hydroquinone, quinone and maleic anhydride to carbon dioxide and water. On the other hand, it has been reported that benzene and benzene derivatives which contain no oxygen (such compounds as toluene and chlorobenzene) can be converted to the corresponding —OH derivatives by heating the former with oxygen or air in the absence of oxidation catalysts but at temperatures between 650 and 750°C.[9]

MALEIC ANHYDRIDE

Downs[10] has pointed out that in the synthesis of organic chemicals, several different inorganic or organic intermediates are usually needed, and frequently the large quantities of the inorganic materials required may exceed the cost of the organic raw material. Catalytic oxidation processes, such as those now used in making maleic anhydride and other benzene oxidation products, approach the ideal for industrial purposes, since only one raw material need be stocked for use; the other is air, which carries no freight or warehousage charges or other costs beyond that of blowing it into the reaction vessel. Maleic acid, before the discovery of its synthesis by oxidation of benzene, was a laboratory chemical and of little practical interest. It is now produced by oxidation of benzene or naphthalene. Maleic acid is one of the reagents indicated in the important Diels-Alder reactions[11] according to which it condenses spontaneously with conjugated diolefins such as butadiene, isoprene, cyclopentadiene and various other unsaturated compounds:

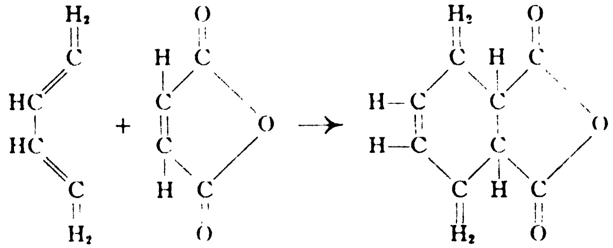
Butadiene + maleic anhydride ——→ tetrahydrophthalic anhydride



By the direct addition of water to the double bond of maleic acid, malic acid can be produced. This edible acid has been suggested as a substitute for tartaric acid in baking powder. Bertsch and Krause[12] report reducing maleic acid electrolytically to produce succinic acid by hydrogenation of the double bond. The yield is said to be approximately 97 per cent of that theoretically possible.[13]

This oxidation of benzene to maleic anhydride or maleic acid is generally effected by the use of catalysts composed of oxides of metals of variable valence (such as iron, vanadium, chromium and tungsten). Zalkind and Zolotarev[14] mixed benzene and air by bubbling the air through liquid benzene at 15°C., and tested the catalytic action of vanadium pentoxide (deposited on pumice) with this mixture. The gases were preheated to 360°C. and reacted at 410 to 430°C. The investigators reported this process gave the highest yields obtained, approximately 15 per cent of maleic acid calculated on the benzene consumed. Unoxidized benzene was recovered by adsorption on cooled silica gel. It was believed that oxidation proceeded as a series of hydroxylations, yielding phenol, hydroquinone, quinone and finally maleic acid.

Jaeger[15] proposes that the effective yield can be increased without the use of recycling pumps by using a series of reaction chambers interspersed in the circuit between a series of condensers. The reaction product of the first chamber would thus pass through a condenser wherein the oxidation products would be extracted and the unreacted gases would pass on to a second converter, a second condenser, and thus through whatever number of converters was decided upon.

Jaeger[16] has also suggested that maleic acid may be produced by the oxidation of heterocyclic compounds such as furan and its derivatives. Thus, furfuraldehyde and air, mixed with exhaust gases from the oxidation, are passed over a vanadium pentoxide-aluminum oxide catalyst at about 370°C. to yield 45 to 75 per cent of the compounds maleic acid and mesotartaric acid. Polynuclear hydrocarbons such as naphthalene may be used as the starting material in the maleic acid synthesis also. Brode and Johannsen[17] suggest that the vapor of naphthalene or acenaphthene and air be passed over vanadium pentoxide catalyst at 400°C. and the resulting mixture slightly cooled. It is then passed over zinc, cadmium or aluminum oxide catalysts and the products (principally maleic acid and benzene) condensed out of the exhaust gases.

PRODUCTION OF PHTHALIC ANHYDRIDE

Phthalic anhydride, important in dye synthesis and other organic syntheses, has become of even greater importance since synthetic resins of the alkyd type have created an excellent market for this substance. The oxidation of naphthalene to produce this substance has, consequently, become of increased importance. As in the oxidation of benzene to its intermediate products of oxidation, the common catalysts in the oxidation of naphthalene to phthalic anhydride are the oxides of the metals capable of more than one valence state. Punnett[18] suggests, for instance, that vanadic oxide and aluminum deposited on alundum be used as the catalytic agent in this type of reaction. The temperature employed is generally somewhat below red heat.[19] Jaeger[20] proposes a similar (vanadium oxide) catalyst supported on diatomite brick. Silicon carbide, titanium carbide or zirconium carbide have been suggested as activators for vanadic oxide catalysts in this reaction[21] and simultaneously serve as supports for the catalyst.[22]

Brode and Johannsen[23] report that one apparatus for the oxidation can be effectively arranged so that the naphthalene vapors and air are led into a catalyst chamber, then to a chamber where the gases are collected, mixed with air, and passed to another catalyst chamber. The exhaust from this second catalyst chamber is mixed with further naphthalene vapor-air mixture, and the gases are passed to a third catalyst chamber (See Fig. 212).

In controlling the proportion of oxygen to naphthalene vapor, Riegler[24] saturates the oxygen-containing gas (air) with naphthalene vapor at a known temperature, then admixes a known quantity of naphthalene-free air to bring the proportions to any desired value. To aid in control determinations of the reaction, Douglass and Jones[25] suggest that a portion of the reacting gases be withdrawn during the process, and the organic constituent be converted completely to oxides of carbon and determined as such. The catalytic converter apparatus is then controlled by these determinations.[26]

PRODUCTION OF BENZALDEHYDE

Parks and Katz[27] have published a report of data accumulated in studies of a series of different catalytic agents for the oxidation of toluene in air. They were particularly interested in the production of benzaldehyde, since this substance is a lower oxidation product than benzoic acid or maleic anhydride, and correspondingly more difficult to obtain in good yield. The industrial price of benzaldehyde is relatively higher in consequence, and it was hoped that a suitable catalyst could be found which would tend to favor the production of the aldehyde. It was thought that the lead derivatives of the metals of the fifth and sixth groups of the periodic table would favor the partial oxidation of the side chain, since tetraethyl lead slows the oxidation of gasoline. Other investigations had indicated that metals of these groups were best suited for the partial oxidation of toluene. Various catalyst supports were tried, and aluminum metal in granular form was selected as most satisfactory. Because of its high heat conductivity the tendency toward formation of hot spots and consequent irregular oxidation leading to carbon dioxide and water was decreased. Good heat transfer is necessary as well as effective cooling, since the reactions involved are highly exothermic. The following equations illustrate this proportionality among the various possible degrees of oxidation:

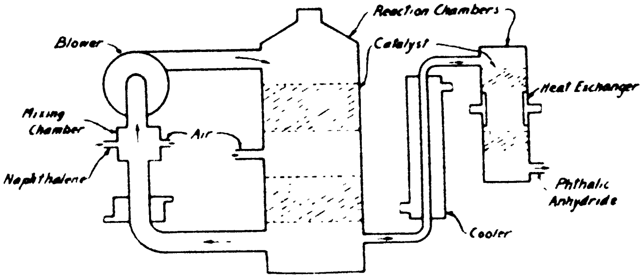

FIG. 212. Sketch of Equipment for Oxidation of Naphthalene to Phthalic Anhydride. (J. Brode and A. Johannsen)

$$C_6H_5CH_3 + \tfrac{1}{2}O_2 \longrightarrow C_6H_5CH_2OH + 39{,}900 \text{ cal.}$$
$$C_6H_5CH_3 + O_2 \longrightarrow C_6H_5CHO + H_2O + 91{,}200 \text{ cal.}$$
$$C_6H_5CH_3 + 3/2\ O_2 \longrightarrow C_6H_5COOH + H_2O + 156{,}300 \text{ cal.}$$
$$C_6H_5CH_3 + 6O_2 \longrightarrow C_4H_2O_3 + 3CO_2 + 3H_2O + 600{,}300 \text{ cal.}$$
$$C_6H_5CH_3 + 9O_2 \longrightarrow 7CO_2 + 4H_2O + 934{,}400 \text{ cal.}$$

In respect to the catalysts it will be remembered that the "gap elements," those possessing more than one oxidation state, have been found most satisfactory, and the hydroxylation theory of oxidation has been most generally accepted in the oxidation of benzene. The hydroxylation mechanism would require the presence of oxygen in the atomic state, and it is found that catalysts removed from the reaction chamber show color shadings indicating various oxidation stages. These investigators conclude that there is an alternate oxidation and reduction of the metallic oxide, atomic oxygen being released in each cycle. The temperature at which a given oxide becomes active in catalyzing the reaction corresponds to the tempera-

ture at which this oscillation to higher and lower oxides takes place. Among the catalysts tried were lead chromate, tungstate and vanadate, uranium tungstates and molybdates with boron carbide, and other salts and combinations of the metals of the groups suggested. Thus it was found that with lead molybdate a maximum of oxidation was obtained at a temperature of 585°C., when 29.5 per cent of the available oxygen was consumed in partial oxidation products, the remainder of the oxygen producing total oxidation products (carbon dioxide and water). Lead chromate became active as a partial oxidation catalyst at 390°C. (2.4 per cent of the oxygen consumed appeared as oxygenated bodies), although using uranium tungstate, even at 425°C., gave no partial oxidation products. A uranium-molybdenum-boron carbide catalyst at 575°C. gave the highest yield of partial oxidation products, that is, 45 per cent. A similar uranium-molybdenum catalyst without the addition of boron carbide yielded (at 525°C.) only 23 per cent partial oxidation products.[28] The apparatus used is illustrated in Fig. 213.

FIG. 213.—Apparatus for Vapor-phase Oxidation of Toluene. (W. G. Parks and J. Katz)

Successful solution-oxidation of toluene to benzaldehyde and benzoic acid has been reported by Berkenheim and his co-workers.[29] The oxidation process in this case is carried out at temperatures of the order of 35 to 40°C. in a sulphuric acid solution, manganese dioxide serving as the source of oxygen. The ratio of benzaldehyde to benzoic acid can be controlled quite accurately, these investigators report, by varying the conditions of time of reaction, temperature, and the ratios of manganese dioxide, sulphuric acid and toluene. Benzaldehyde can be prepared without admixture of benzoic acid by carrying out the reaction at 35 to 40°C. in the presence of 65 per cent sulphuric acid for 6 hours, using 4 parts (by weight) of sulphuric acid and 1 part of manganese dioxide. Toluene is converted to the aldehyde (20 to 22 per cent), and 40 per cent of the toluene can be recovered unchanged. At temperatures of 70 to 75°C., using more sulphuric acid (13 to 14 parts of 50 per cent acid), benzoic acid is the principal product. According to these investigators, manganese dioxide obtained in various ways as by-products can be used satisfactorily in this preparation.

---

[28] These yields were calculated on the basis of the oxygen consumed.

[29] A. M. Berkenheim, E. V. Yavorskaya, O. P. Al'bitzkaya and T. F. Dankova, *J. Applied Chem. (U.S.S.R.)*, 1934, 7, 778; *Chem. Abs.*, 1935, 29, 2522; *Brit. Chem. Abs.* B, 1935, 137.

Since benzaldehyde is so readily oxidized to benzoic acid, other investigators[30] have suggested that a milder oxidizing agent be used. Thus, carbon monoxide may be used with benzene, the carbon monoxide adding to the ring to form the aldehyde. The proposed method suggests passing carbon monoxide into an autoclave containing aluminum chloride and benzene which has been saturated with hydrogen chloride at atmospheric pressure. A reaction temperature of 20 to 50°C. is maintained, and the reaction product discharged gradually into water maintained at 10 to 60°C. by circulation of tap water through cooling coils. The investigator reports that the use of ice water, or refrigeration maintaining temperatures near 0°C. is unnecessary.

PRODUCTION OF BENZOIC ACID

Benzoic acid is produced in two types of oxidation processes: by direct oxidation of toluene to the acid, and by oxidation of naphthalene to phthalic anhydride followed by decarboxylation of the dicarboxylic acid to benzoic acid.

The oxidation of toluene to benzoic acid requires powerful methods of cooling, due to the large amounts of heat released during the reaction. Jaeger[31] has suggested a method illustrated in Fig. 214. He has also proposed that an inhibiting vapor, such as carbon tetrachloride, be added as an inert protective.[32] In the oxidation, this investigator found that potassium vanadyl vanadate at 380 to 390°C. acts as a specific catalyst, tending to oxidize the side chain rather than the ring structure. He recommends that milder catalysts, such as a diluted zeolite containing tantalum, molybdenum or tungsten at somewhat higher temperatures (450°C.), be used if aldehydes are desired.[33] It has been reported that the activity of vanadium oxide in this catalytic action can be increased by the addition of silica gel.[34] Jaeger[35] produced a catalyst for this and similar oxidation reactions by mixing together three solutions, one composed of a suspension of "Celite" earth in a water-glass solution, the second a potassium vanadate solution, and the third a solution of potassium aluminate. The mass is converted to a gel by the addition of sulphuric acid and this gel filtered and dried at temperatures below 100°C. It is then broken into lumps, hydrated by trickling water over it, and leached with a 3 per cent sulphuric acid solution. The leached mass is calcined in air mixed with sulphur dioxide gas at 420 to 500°C.

Toluene may be partially oxidized in solutions, particularly solutions of chromates and dichromates, it has been reported. The reaction is carried out under pressure and at temperatures above 100°C. (but below 360°C., the critical temperature of water). The dichromates of the alkali metals should be present, it is said, since in this way the sodium hydroxide formed during the reaction which reduces the chromium is neutralized by the dichromate rather than by the benzoic acid formed. Photochemical reactions also may be employed in this type of partial oxidation. Anthraquinone is generally employed as the catalyst, according to Nozicka,[36] but various auxiliary catalysts may be employed to improve the process.

He found, for instance, that activated carbon or an oxide or salt of copper, bismuth, iron, vanadium or silver acts as a promoter. The vapors of toluene and anthraquinone mixed with oxygen may be passed over such a catalyst as those suggested, while the gases are strongly irradiated to produce benzoic acid. Similarly, this type of catalyst will promote the reaction of benzene and hydrogen chloride to form chlorobenzene, it is stated.

The second oxidation method of producing benzoic acid mentioned earlier in this chapter is that which involves the oxidation of naphthalene to phthalic anhydride followed by decarboxylation to benzoic acid. Jaeger[37] recommends passing phthalic anhydride, hydrogen and carbon dioxide over sodium chloride on quartz at 360 to 400°C. If phthalic anhydride and carbon monoxide are passed over copper on pumice at this temperature, the product is largely benzaldehyde. With other catalysts such as iron oxide-sodium chloride, aluminum vanadate, hydrated copper aluminum silicate or iron carbonyl, a mixture of benzoic acid and benzaldehyde is produced. This investigator has also suggested passing the oxidation products of naphthalene mixed with water vapor directly over a strongly alkaline contact mass (e.g., copper carbonate-calcium hydroxide on pumice at 320 to 400°C.) for the preparation of benzoic acid.[38] He[39] has further suggested beryllium oxide at 350 to 450°C. as a catalyst in this decarboxylation. According to Brode and Johannsen,[40] the use of lead oxide as catalyst allows the reaction to

On the other hand, Brode, Johannsen and Drossback (German P. 608,075, 1935, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1935, **29**, 2548) have suggested an analogous reaction for production of naphthoquinone and benzene. In this case the

take place at a temperature as low as 250°C., although temperatures up to 500°C. are suggested. The same investigators also proposed bismuth and cadmium oxides, and iron oxide activated by zinc or cadmium oxide. According to Scharff and associates,[41] in the decarboxylation of phthalic anhydride to benzoic acid, cooling considerations are of little importance, since there is small heat exchange in this reaction. Thus, these investigators suggest that the oxidized naphthalene vapors containing phthalic anhydride be passed directly from the reaction chamber (leaving this zone at a temperature of about 400°C.) and, with only slight cooling, contacted with the decarboxylation catalyst. This latter conversion to benzoic acid is, however, attended with the difficulty that organic sulphur compounds present as impurities tend to form sulphuric acid. The inorganic acid is considered to poison the catalysts used in the decarboxylation. They suggest, therefore, that the catalyst be either moved countercurrently to the reacting gases, or that two catalyst stages be employed. In the first proposed method, the raw gases meet first the nearly exhausted, and sulphuric-acid-saturated, catalyst, gradually depositing sulphuric acid as they reach progressively fresher catalyst. In the second method, the gases would first be contacted with a cheap and inferior catalyst such as pumice granules or zeolites, catalysts which will absorb the sulphuric acid.

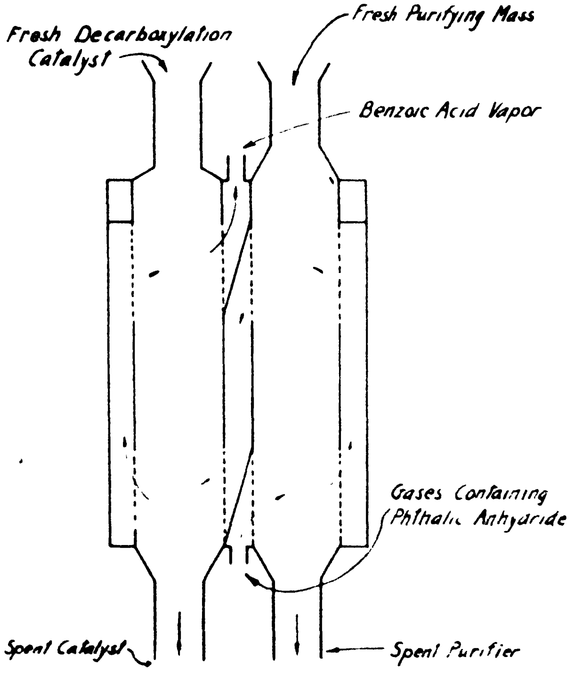

FIG. 215. Sketch of Apparatus for Decarboxylation of Phthalic Anhydride to Benzoic Acid. (M. Scharff, J. Brode, A. Johannsen and J. Reichart)

---

products of the catalytic oxidation of naphthalene are led (without isolation) over a decarboxylation catalyst such as cadmium oxide-aluminum oxide at a temperature of 380°C. These investigators have also suggested passing the oxidation products over a second oxidation catalyst with further admixture of air, thus producing maleic acid and benzoquinone.

[41] M. Scharff, J. Brode, A. Johannsen and J. Reichert, U. S. P. 1,988,876, Jan. 22, 1935, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1935, **29**, 1835.

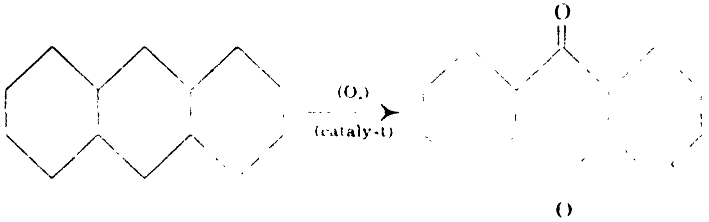
The purified gases are then contacted with a more expensive and highly active catalyst.[42] (See Fig. 215).

Jaeger[43] finds that the metal salts of phthalic acid such as zinc phthalate or nickel phthalate can be similarly broken to yield benzoic acid and some benzaldehyde. Thus zinc phthalate in the presence of quartz is heated with hydrogen to 325-410°C. to yield largely benzaldehyde, but with steam at 360 to 400°C. benzoic acid is the principal product. The efficiency of the reaction is reported to be quite high; with nickel phthalate, hydrogen and steam at 350°C. the yield is 78 per cent of the theoretical quantity of benzoic acid. Daudt[44] reports that phthalic anhydride and water vapor react at temperatures of 175 to 350°C. in the presence of nickel phthalate catalyst to yield benzoic acid.

Jaeger[45] has also suggested that methyl alcohol and phthalic anhydride be passed over a zinc oxide catalyst (at 380 to 400°C.) to produce methyl phthalate and benzoic acid. In a somewhat similar manner dimethyl (or diethyl) phthalate, passed over aluminum vanadate, yields methyl (or ethyl) benzoate and some benzaldehyde.

PRODUCTION OF ANTHRAQUINONE

Various investigators have reported methods for the oxidation of anthracene to anthraquinone. This reaction may be represented as follows:



Anthracene Anthraquinone

Schmidlin[46] found that vanadium oxide or iron or silver vanadate served as catalysts for the air oxidation of fused anthracene under normal pressure. Jaeger[47] also reports that iron vanadate or iron-manganese vanadate makes a good catalyst for this reaction but recommends the addition of an alkali or alkaline earth metal salt, such as one of potassium or calcium. Crude commercial anthracene at a temperature of 340 to 440°C. is mixed with air and passed over this catalyst mass to form anthraquinone. Pietzsch[48] has proposed an apparatus for this type of oxidation wherein the gaseous reactants are passed through annular spaces between an inner tube containing catalyst, and an outer wall surrounded by a heating bath. The flow is then reversed and the gases led countercurrently through the catalyst tube where reaction takes place. DeRewal[49] reports that the vapor phase oxidation of anthracene can be catalyzed by the oxides of nitrogen, using air or other oxygen-containing gas as the source of oxygen.

---

[42] C. Conover (U. S. P. 2,006,335, July 2, 1935, to Monsanto Chem. Co.; *Chem. Abs.*, 1935, **29**, 5460) has suggested a different type of decarboxylation, using chromium chloride as the decarboxylation catalyst in the presence of dry hydrogen chloride to produce benzoyl chloride from phthalic anhydride. The metal chloride is added to the acid anhydride at a temperature above 200°C., while the dry hydrogen chloride is passed in.

On the other hand, it has been suggested that alkali chromates be made the source of oxygen in producing anthraquinone from anthracene. A solution of the chromates may be made acid by addition of an acid weaker than acetic, such as, for instance, carbonic acid. The anthracene is heated under pressure with this solution, to produce anthraquinone and chromic hydroxide.[50]

ELECTROCHEMICAL OXIDATION OF AROMATIC HYDROCARBONS

In addition to the catalytic methods of oxidation that have been suggested, a number of investigators have found that in some instances electrochemical methods may be employed successfully. McKee and Heard[51] reported an investigation of the oxidation of benzoin in alkaline solutions of sodium aromatic sulphonates. They found that a nickel electrode permitted good efficiency in this oxidation, while in strongly acid solutions naphthalene depolarized a graphite electrode with the formation of quinone and various phenolic products. The solvents used by these investigators were sodium xylene- and cumene-sulphonates. These compounds bring into aqueous solution a considerable variety of water-insoluble organic compounds, including toluene, naphthalene, anthracene, hydroquinone, borneol and non-aromatic compounds such as linseed acids and oleic acid. In addition to making possible the oxidation of these dissolved compounds by electrochemical action, the sulphonates also aided electrochemical halogenation of toluene.

Palfreeman and Knibbs[52] report oxidation of benzene to benzoquinone by adding benzene continuously to a 10 per cent aqueous solution of sulphuric acid in an undivided cell of lead and lead dioxide anode and a water-cooled lead cathode. The acid-benzene mixture was stirred at such a rate as to assure distribution without emulsification. The oxidation product (benzoquinone) in dilute benzene solution overflows from the surface of the acid into a reduction vessel containing iron and an aqueous iron salt kept above the boiling point of benzene. The quinol formed passes into the aqueous phase, while the benzene is distilled, condensed, and returned to the electrolytic cell. Schwaebel[53] suggests that one solution of the problem of getting good contact between the hydrocarbon and the active electrode may be to inject the benzene or other hydrocarbon into the aqueous electrolyte in a finely divided state in such a manner that it rises over the surface of one of the electrodes. For instance, the compound may be forced in through a nozzle arranged beneath an inclined anode of large surface. The benzene then rises across the anode surface to the surface of the aqueous electrolyte, and a pump recirculates the superincumbent liquid through the nozzle. Thus benzene may be oxidized to benzoquinone, or toluene to toluquinone. Analogous electrolytic reduction may be used to convert benzoquinone to hydroquinone.

Plotnikov[54] and co-workers have investigated the oxidation of toluene in ether-water solutions of phosphoric acid and report that the ring and side chain are both attacked. Benzaldehyde can be produced in somewhat better than 1 per cent yields (1.08 per cent) when using current densities of 0.0112 amperes per square centimeter, although low current densities of the order of 0.0065 amperes per square centimeter yield only about 0.1 per cent. Kirk and Bradt[55] report that nitration of toluene can be speeded and made more complete by electrochemical action. Concentrated nitric and sulphuric acids and toluene were placed in the anodic compartment of a cell with a porous diaphragm and a platinum electrode. A nitration yield of 46 per cent without electric current was increased to 48.3 per cent by the application of direct current. However, mixtures which normally give nitration yields higher than 50 per cent do not give better yields with current. The presence of manganous, bismuth, ceric, mercuric, chromic and vanadic ions increase nitration, particularly manganous ions, but tungstic oxide decreases nitration, though all of these serve to increase oxidation. Fichter and Rosenzweig[56] studied the electrochemical reactions of *p*-fluorotoluene and found that although this halogenated toluene is readily oxidized to fluorobenzoic acid, the intermediate aldehyde could not be isolated. Fichter and Müller[57] report that the use of wetting agents such as isopropylnaphthalenesulphonic acid to disperse hydrocarbons (e.g., mesitylene) in dilute aqueous sulphuric acid leads to higher yields of oxidation products. The products of electrolysis (with a current density of 0.016 amperes per square centimeter) on a lead dioxide anode were mesitylenealdehyde, mesitylenic acid, *o*-hydroxymesitylenic acid, uvitic acid, mesitol, 2,6-dimethylbenzoquinone, acetic and formic acids and carbon dioxide. Separate experiments on the individual intermediate products established the course of the reaction. A 13 per cent yield of mesitylenic acid was obtained on the lead dioxide anode, and 6 per cent on a platinum anode in a mixture of 40 per cent nitric acid and 50 cc. of glacial acetic acid plus the wetting agent.

Drozdov and Drozdov[58] suggest oxidizing anthracene to anthraquinone electrochemically in a dimethylketone-sulphuric acid solution. They report that in this solution the hydrocarbon combines directly with oxygen at the anode to yield anthraquinone, a reaction which does not occur when using suspensions of anthracene in sulphuric acid. In the latter case, a catalyst such as cerium sulphate or potassium dichromate is needed to transfer the active oxygen, the electrochemical action serving to regenerate the oxidizing agent. Cerium sulphate is a more active transfer agent than potassium dichromate, but the products obtained are contaminated to a greater degree by higher oxidation products of anthracene than is the case when potassium dichromate is used.

Miscellaneous Oxidation Reactions of the Aromatics

Jaeger[59] has reported that fluorene can be oxidized with air in the presence of vanadic oxide catalysts in a manner similar to the oxidation of naphthalene. The reaction takes place between 300 and 500°C. to yield fluorenone and a small amount of phthalic and maleic anhydrides. These latter products can be removed from the oxidation mixture by cooling the exhaust gases to just below 190°C.

Duckert[60] reports that acenaphthene can be oxidized to naphthalic acid and acenaphthenequinone to the extent of about 2 per cent by the use of oxygen (as oxidizing agent) and a catalyst. The best conditions were found to be 3 to 5 kilograms per square centimeter pressure, a temperature of 300°C. using as catalyst manganese nitrate, and dissolving the acenaphthene in dichlorobenzene. Kiprianov and Dashevskii[61] found that the oxidation of acenaphthene produced a small quantity of acenaphthenequinone and some naphthalic acid anhydride. A considerable quantity of the quinone could not be separated from the acid anhydride by extraction in aqueous sodium carbonate or sodium acid sulphite solutions, due to the formation of mixed isomorphic crystals of the two organic substances. The isomorphic crystals appeared to consist of alternate layers differing in chemical properties. Extraction and separation was possible by using the sodium salts in aqueous solutions under pressure and at elevated temperature, or by dissolving the salts in hot nitrobenzene. The rather small yields of the quinone were raised by this extraction method.

Dashevskii and Karishin[62] treated acenaphthene (5 gms.) with ammonium dichromate (19 gms.) in 95 per cent acetic acid solution (200 cc.) and obtained a 71.1 per cent yield of acenaphthenequinone, along with only 7.5 per cent of naphthalic acid.

It has been reported that acenaphthene can be dehydrogenated to acenaphthylene by certain catalysts typified by solid, non-reducible heavy-metal compounds such as zinc molybdate and zinc oxide, although magnesium oxide, crystalline silicon or graphite are also suggested. The acenaphthene, with a diluent such as nitrogen or water vapor, is passed over the catalyst at a temperature of 600 to 750°C. under atmospheric pressure.[63]

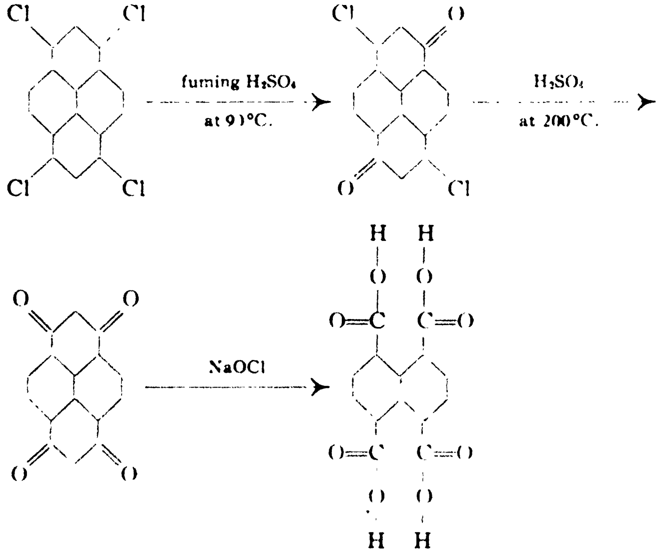
More complex aromatic acids may be made by indirect oxidation processes. Thus naphthalene-1,4,5,8-tetracarboxylic acid and its derivatives may be prepared from pyrene. The method proposed involves a preliminary chlorination of pyrene, to form the tetrachloropyrene. This is oxidized in three stages; first in 20 per cent fuming sulphuric acid at 90°C., then in concentrated sulphuric acid at 200°C. The pyrenequinone formed by these processes is then oxidized by sodium hypochlorite, with rupture of two of the rings, to form naphthalene-1,4,5,8-tetracarboxylic acid.



If instead of the tetrachloropyrene, a hexachloropyrene, obtained by a more exhaustive chlorination of pyrene, is used as the starting material, and the third and final oxidation is carried out using nitric acid in place of the hypochlorite solution, a dichlorinated tetracarboxylic acid is obtained. The product appears to consist of a mixture of two acids; the provisional formula assigned to this product is as follows, in which one X represents an atom of chlorine, the other X a hydrogen atom:[64]

Selenium dioxide has been suggested as the oxidizing agent in syntheses involving such hydrocarbons as polynuclear aromatics containing a methyl or methylene group. Thus 2-methylbenzanthrone can be heated under reflux with acetic acid and selenious acid to yield benzanthrone-2-aldehyde.[65] Fisher[66] reported studies of the oxidation of nitrobenzene compounds and benzyl halides refluxed with selenium dioxide. The conditions required for the oxidation of nitrotoluenes are fairly rigorous; 2,4-dinitrotoluene and 2,4,6-trinitrotoluene were unattacked by selenium dioxide in boiling alcohol though oxidation was possible at somewhat higher temperatures. However, *p*-nitrobenzyl bromide was oxidized readily to nitrobenzaldehyde, and benzyl chloride yielded benzaldehyde and a small quantity of benzoic acid. Nitrobenzal bromide (*p*-) was not as readily oxidized as was the benzyl compound but yielded *p*-nitrobenzoic acid. More complex aromatics such as diphenylmethane, 4,4′-dinitrodiphenylmethane and triphenylmethane were not oxidized by selenium dioxide in boiling alcohol, though at higher temperatures the di- and triphenylmethanes were oxidized to benzophenone and triphenylcarbinol, respectively. Firth and Gething[67] found that selenium compounds act as catalysts for oxidation by hydrogen peroxide. Thus, the oxidation of benzaldehyde in the presence of hydrogen peroxide alone is slow under ordinary conditions, but the addition of a small amount of selenium oxychloride materially accelerates the reaction.

Several reactions have been developed whereby carbon monoxide can be directly added to aromatic compounds, which, although not strictly an oxidation process, yields various oxyaromatics. Zerbe and Jage[68] have studied the reactions of various phenol derivatives and homologues with carbon monoxide under pressure and heat. It was found that in the presence of alcohol (methyl or ethyl) sodium phenolate reacts with carbon monoxide to form ethers. Pressures above 30 atmospheres make this reaction quantitative, according to Zerbe and Jage, carbon monoxide absorption beginning at 130°C. and best yields resulting at 180°C. In general, the phenol homologues are more reactive in this synthesis than is phenol itself, the reactivity being changed by the amount and nature of the basic or acidic substituent. It is suggested that carbon monoxide adds to produce a formic ester intermediate. Hey[69] reports that benzene reacts with carbon monoxide in the presence of hydrogen chloride and aluminum chloride-cuprous chloride catalyst to yield benzaldehyde, benzoic acid, and a small quantity of anthracene. Larson[70] suggests that in the aluminum chloride-catalyzed condensation of carbon monoxide and benzene to benzaldehyde, a complex of aluminum chloride and the aldehyde can be used as the catalyst in the initial stages of the reaction. Thus the reaction is begun with fresh benzene and carbon monoxide plus aluminum chloride-aldehyde complex from previous reactions and later completed by the addition of fresh aluminum chloride.

An indirect method permitting the addition of carbon dioxide to naphthalene and its derivatives has been reported. In this case naphthalene is reacted with metallic sodium in the presence of a stable aliphatic monoether (e.g., dimethyl, methylethyl or methylpropyl ether) or mixtures of these with other nonreactive solvents. The product, 1,4-disodiumnaphthalene, is highly reactive and hydrolyzes to form dihydronaphthalene and when treated with carbon dioxide yields the alkali metal salt of dihydronaphthalenedicarboxylic acid.[71]

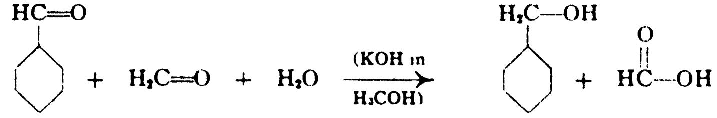
Davidson and Bogert[72] have reported making benzyl alcohol by the crossed Cannizzaro synthesis. The aromatic aldehyde (e.g., benzaldehyde) is introduced to a solution of methanol and formaldehyde at 65°C. and potassium or sodium hydroxide added, the heat of reaction being absorbed by cooling water to maintain the temperature between 65 and 70°C. The mixture is then heated at 70°C. for 40 minutes and finally refluxed for 20. The aromatic alcohol (benzyl alcohol) is formed in 85 to 90 per cent yield with about 2 to 5 per cent of the corresponding aromatic acid. The reaction is effective also with other aldehydes, permitting the preparation of anisyl, piperonyl and veratryl alcohols.



Separation and Purification of Aromatic Oxidation Products

The problem of separation and purification of the complex mixture of oxidation products resulting from catalytic oxidation processes may be divided into two general phases: separation of the products, and decolorization. The latter is generally effected during the purification, but certain stubborn traces of substances with great coloring power must sometimes be treated separately. The distillable color-bearing substances which come over with phthalic anhydride, for instance, may be removed by prolonged (several hours) heating of the anhydride at about 285°C., but Conover[73] has suggested that this process may be improved by the addition of acids such as lactic, tartaric or citric, or of acid-forming substances such as glycerol. Smith[74] has found the ultraviolet light from a mercury arc aids in decolorization, and it is reported to be sufficiently effective to make further distillations unnecessary in some cases. It has been suggested further[75] that phthalic anhydride vapor be diluted with an inert gas, such as carbon dioxide or nitrogen, so that the anhydride is precipitated in the form of finely divided solid particles, and recovered in this manner.

In the separation of such materials as benzoic acid, phthalic and maleic anhydride and other complex oxidation products, general methods depend on fractional distillation, differential solubility or differential activity. Frequently the distillation is conducted using a compound of the substance to be purified rather than the material itself. Thus, Jaeger and Daniels[76] suggest reacting the crude phthalic anhydride with an ammonium base compound (e.g., ethanolamine) which is capable of reacting with the acid anhydride to form ammonium phthalate. Water is evaporated and the residue heated to form and sublime pure phthalimide. An analogous method involving fractional solidification rather than distillation has been reported. Conover[77] suggests melting the crude product, then cooling it in an undisturbed condition. Crystallization takes place precipitating a purified solid phase while the impurities remain in the liquid, permitting separation. Riegler[78] proposes precooling the vaporous products before condensation. The precooling temperature is adjusted to a controlled value above the dew-point of the mixture with respect to the product. In the products of naphthalene catalytically oxidized for production of phthalic anhydride, the dew-point of phthalic anhydride (though varying considerably since it is dependent on the nature and efficiency of the catalyst, the naphthalene-air ratio originally used, and other factors) is generally in the neighborhood of 115 to 130°C. Thus, a primary cooling apparatus may be used wherein the heat energy of the hot exhaust gases is taken up in boiling water under slightly more than atmospheric pressure. The gases then pass into a condensing chamber where the temperature drops below the dew-point, precipitating the anhydride. The method is said to be advantageous in that it permits the use of a small, closely controlled primary condenser in absorbing the major portion of the heat energy of the exhaust gases. This also permits easy control of the precipitating condenser which is thus required to lower the temperature of the gases to an extent of only a few degrees. The investigator[79] has suggested that the precooled gases (at 120 to 135°C.) be passed through a long, narrow, externally cooled tube, for instance. The tube is fitted with a screw-type scraper, which serves to dislodge the deposit, and simultaneously convey it to the discharge end. At the same time, the flow of gas through the tube is made turbulent by the scraper, resulting in small, homogeneous crystals, it is reported. The gases pass finally through dust bags.

Desai and Patel[80] report an investigation of the solubilities of benzoic, cinnamic, salicylic, phthalic and succinic acids in 14 solvents of various polarities. It was found that in slightly polar solvents, the solubilities decrease with increasing polarity of the solutes, phthalic and succinic acids being scarcely soluble. Solubility increases with polarity in the aromatic hydrocarbons, cyclohexane and carbon tetrachloride. It is suggested that benzoic, cinnamic and salicylic acids form readily dissociable solvates with alcohols, while phthalic and succinic acids form hydrates with water which cause irregularities in the general behavior of these substances. The investigators concluded that the order of solubility is that of the polarity of the solvents in the case of the aromatic hydrocarbons, cyclohexane and carbon tetrachloride, but that this general relationship does not hold with more polar solvents. Chloroform was irregular in all cases. Acetone and butyl alcohol were abnormal in some cases.

This type of differential solubility is used in purifying the various products of aromatic oxidation, either directly applied to the substance or by first forming a separable salt. Jaeger and Daniels[81] have suggested extracting the products with two or more organic solvents and water. The crude compounds are taken up in water solution, the solution is extracted first with a solvent dispersible in water (e.g., hydroxytoluic acid) and this mixture is in turn extracted with a solvent such as benzene which is miscible with the non-aqueous solvent and indispersible in water. The purified acid (maleic, fumaric, phthalic or naphthalic) is recovered from the aqueous solution. Jaeger[82] has also proposed that benzoic and phthalic acids may be separated by washing the mixture with benzene or toluene, in which the benzoic acid is the more soluble. The use of monochloronaphthalene or solvent naphtha in an analogous process has been suggested.[83] On the other hand, Bentley and Catlow[84] have proposed that a double compound be formed by one or more of the constituents of the mixture to be separated and this compound separated out by fractional crystallization. Thus cresols may be reacted with an aromatic amine such as benzidine (paradiaminobiphenyl) and the resulting compound separated from impurities by crystallization. Witzel[85] suggests that in working with the oxidation products of furfural, alkali can be added to form maleic and tartaric salts which can be separated by crystallization from water solution.

[81] A. O. Jaeger and L. C. Daniels, U. S. P. 1,930,054, Oct. 10, 1933, to Selden Co.; *Chem. Abs.*, 1934, **28**, 179; *Brit. Chem. Abs.* **B**, 1934, 751.

Some investigators have suggested accomplishing separation of the impurities by a secondary oxidation process, choosing such conditions as will destroy the undesirable compounds without seriously attacking the desired product. Jaeger and Daniels[86] found this separation applicable where the salts of the desired substance are less readily oxidized by hypohalites than are the corresponding salts of the impurities. The sodium salts (of benzoic, naphthalic or phthalic acids, for instance) are formed, and an aqueous dispersion of these salts is treated with sodium hypochlorite (or hydrogen peroxide). The salts are then converted to esters and separated in the usual manner (as by distillation). Bertsch and Krause[87] report an analogous purification of succinic acid (produced by electrolytic reduction of maleic acid) by the action of alkaline potassium permanganate, followed by decolorization (with charcoal) and filtering. Volkhin[88] reports that phthalic anhydride was purified by maintaining it at 180 to 280°C. for 3 to 4 hours and then adding sodium or calcium chloride with ferric oxide or oxides of other metals (e.g., lead oxide, cuprous oxide). The temperature is maintained at 200 to 280°C. for a further period of 3 to 4 hours and the mixture then distilled in vacuo or blown with air to recover the phthalic anhydride.

On the other hand, Conover[89] suggests separating benzoic and phthalic acids by a partial neutralization with a salt such as sodium carbonate, taking advantage of the fact that phthalic acid is stronger than benzoic. The separation is completed by distilling the resulting mixture with superheated steam.

According to Jaeger[90] most of the impurities present in phthalic anhydride produced by the vapor phase oxidation of naphthalene which are volatile at the sublimation temperature of the acid anhydride are unsaturated substances. He proposes that these substances can be eliminated by contacting them with polymerization catalysts, bringing about the formation of larger and non-volatile molecules. The crude anhydride is heated under atmospheric pressure to its boiling point, or under 3 to 5 atmospheres pressure (when it may be heated to boiling or somewhat less than the boiling point under this pressure). If pressure is used and the vapors are contacted with a polymerization catalyst (aluminum chloride, zinc chloride or activated carbon), the purification process is said to be completed in one to two hours. After the lapse of this period, the refluxing polymerization still is tapped and the phthalic anhydride sublimed over. If atmospheric pressure is used and no catalyst employed, the mass should be maintained at its boiling point (284.5°C.) for 6 hours.

Chapter 42

Production of Acids from Petroleum Hydrocarbons

Acids can be obtained by the oxidation of petroleum hydrocarbons by either liquid- or vapor-phase operations. A variety of agents, such as air or oxygen, nitrogen tetroxide, or ozone, have been recommended. In addition to acids, other oxygenated hydrocarbons, such as alcohols, ketones, aldehydes, and esters, are formed and in many instances the conditions under which reaction takes place determine which product will be secured in the largest proportion. In this chapter are discussed those methods applicable to liquid hydrocarbons, particularly to the higher-boiling distillates. Procedures employed with gaseous hydrocarbons have been described previously (see Chapters 37, 38 and 39) and those for solid petroleum hydrocarbons (e.g., paraffin wax) are given later (Chapter 43).

OXIDATION OF LIQUID HYDROCARBONS IN THE LIQUID PHASE

The oxidation of saturated hydrocarbons of petroleum origin, with air and oxygen, has been studied by Burwell.[1] Both liquid and solid materials were oxidized under pressures of 200 to 500 pounds per square inch and at temperatures below the thermal decomposition points of the hydrocarbons, in most cases not above 160°C. Fairly large batches (200 or more pounds) of hydrocarbon materials were oxidized. Those stocks rich in straight-chain hydrocarbons oxidized readily without catalysts, whereas the latter were needed when dealing with mixtures in which other types of hydrocarbons represented the major portion of those present. As catalyst, manganese oleate or a portion of unsaponifiable, partially-oxidized hydrocarbons from a previous treatment was used.

When paraffin wax, melting at 122-124°F. and averaging 24 carbon atoms, was oxidized under the above conditions, most of the acids formed averaged 12 to 14 carbon atoms. On the other hand, by oxidizing distillates from Pennsylvania petroleum, fewer acids and a larger percentage of esters resulted. Monobasic, as well as some dibasic, acids were obtained from the solid paraffins, formic and acetic acids representing 10 to 15 per cent of the total products, with the former predominating. Because of this fact, Burwell concluded that primarily oxidation takes place on the beta-carbon atom, second preference being on the gamma-carbon atom instead of the alpha-carbon.[2] This, he believed, resulted first in the formation of alcohols, and later ketones, which oxidized further, with cleavage, to give acids of lower molecular weight. The reactions are illustrated by the following equations:

$$

Hydroxy-acids, lactones, alcohols, ketones and esters were also found among the oxidation products. In some cases esters, representing 60 to 75 per cent of the oxidized material, were obtained, which were difficultly saponifiable and were believed to be derived largely from secondary and tertiary alcohols. Although the acids made from the lighter distillates possessed very disagreeable odors, this objectionable feature could be eliminated to a considerable degree by steam distillation. A fraction of these acids boiling as high as 300°C. (572°F.) did not become very viscous even when cooled to —60°F. The corresponding lead, manganese and cobalt salts were readily soluble in gasoline and have found some use as driers.

Various modifications of the above procedure for oxidizing petroleum hydrocarbons have been employed. For example, transformer oil, subjected to a stream of air (for 6 months) at 110-115°C. gave a humic acid-like product which contained numerous hydroxyl and methoxyl groups, and on further oxidation with potassium permanganate yielded benzene-carboxylic acids.[3] On the other hand, if the oxidation of petroleum oils is carried out in several stages of 12 to 24 hours duration each, using calcium naphthenate as catalyst, water-white acids are obtained.[4] According to Plisov and co-workers[5] calcium naphthenate catalyzes the oxidation of gas oil at mild temperatures (115 to 120°C.) to produce hydroxy acids. In a method described by these workers, a yield as high as 90 per cent was reported. The hydrocarbon was mixed with 0.2 per cent calcium naphthenate, and conducted with air through an electrically heated glass tube. The reaction product was agitated with 20 per cent sodium hydroxide, and the mixture centrifuged for 5 minutes to bring about separation. The alkaline solution was extracted with petroleum ether to remove unsaponifiable material, and the raffinate decomposed to yield the free acids. These investigators report that good separation may be obtained by selective solvent action of petroleum ether, taking advantage of the fact that the hydroxy acids are insoluble in this hydrocarbon solvent. In another procedure, after the oxidation is partially completed the conditions are made less intense, for instance, by lowering the temperature, so that secondary reactions involving the first-formed organic acids are retarded.[6] Also by stopping the reaction while some unoxidized material still remains, the formation of polybasic acids is avoided.[7]

The oxidation of a petroleum oil may be made to yield not only the higher oxidation products such as aldehydes and acids, but also lower oxidation products suitable for use as automobile fuels, Penniman[8] states. This investigator proposes an oxidation process which involves passing air through a deep layer (more than three feet in depth) of oil at a temperature between 315 and 482°C. Pressure greater than atmospheric is recommended. Under these conditions, the air is completely deoxygenated before reaching the surface of the liquid. The converted products of the reaction separate into two layers. The lower aqueous layer consists of a water solution of alcohols, acids, aldehydes and ketones. The upper layer is reported to yield a motor fuel of high antiknock value. This oxidation is said also to remove sulphur compounds as sulphur dioxide. Likhushin, Nasumyan and Levkopulo,[9] working with a specimen of Surakhany fuel oil, found that the most favorable temperature for its air-oxidation was 130°C. while the best air rate was 0.3 cubic meters per hour per kilogram of feed stock. Several catalysts were employed, the best of which was sodium naphthenate. This was needed only for initiation of the reaction. They found also that refined oils gave better results by oxidation than did untreated oils. Both, however, exhibit induction periods which are much longer for the latter types of oils.[10]

Keunecke and Werner[11] report that liquid-phase oxidation of hydrocarbons (containing 10 or more carbon atoms) may be inhibited to some extent by the presence of polymerizable impurities. These investigators suggest that if the liquid material to be oxidized is pretreated with approximately 3 per cent of an anhydrous hydrolyzable halide (e.g., aluminum chloride, boron trichloride or silicon tetrachloride), the undesirable substances are precipitated as polymerization products. In some cases it is advantageous to subject the liquids to a desulphurizing treatment prior to oxidation.[12] This is effectively accomplished by hydrogenation under pressures of 5 to 200 atmospheres and at temperatures of 200 to 350°C. Sulphur is removed as hydrogen sulphide and the unsaturated compounds are partially or completely converted into the corresponding saturates. In still other instances, hydrogenation may be substituted by a sulphonation treatment.[13] After extraction of the sulphonic acids, the oil is then subjected to oxidation at 96-115°C. in the presence of a manganese or calcium catalyst. Other contact agents which have been employed in liquid-phase operations include lithium oleate and aluminum stearate, sodium and aluminum palmitates[14] and alkaline-earth carbonates or mixtures of alkaline-earth oxides and alkali carbonates.[15] Also compounds containing several condensed nuclei, or derivatives of these, have served as catalysts in the photochemical air-oxidation of hydrocarbons,[16] as for example, dihydrodianthrone in the transformation of petroleum to fatty acids. Activated carbon, lead, mercury and zinc compounds have been used as oxidation catalysts.[17] Plisov and Goldovskii[18] state that solar oils can be oxidized by air without the aid of a catalyst. The crude oil was atomized together with steam, into a reactor at 210 to 220°C. The distillate obtained consisted chiefly of higher fatty acids, in good yields. The total yield may be increased when water vapor is absent, but the quality of the product

under these conditions is poorer. A second oxidation of the unreacted oil also results in improved yields.

OXIDATION OF LIQUID HYDROCARBONS IN THE VAPOR PHASE

Klatt[19] has reported experiments on the vapor-phase oxidation of a kerosene oil. The oxidation was carried out in an electrically heated steel tube packed with various catalysts, the resulting vapors then passing into a condenser arranged for very rapid cooling of the gases. It was believed that rapid cooling would minimize secondary reactions. Manganese dioxide, vanadium pentoxide, iron and brass turnings and aluminum scraps were tested for catalytic activity. The data led him to believe that vanadium is most suitable for the reaction. Manganese dioxide leads to pyrolysis rather than to oxidation, it was found. The investigator concluded that the optimum conditions required the presence of steam, vanadium oxide catalyst, and comparatively mild temperatures (250 to 500°C.). The addition of steam to the air-hydrocarbon mixture served to hasten condensation of the water-soluble compounds produced, and to minimize secondary reactions. Klatt and Jelinek[20] oxidized a specimen of Russian kerosene, containing a large proportion of naphthenes, in the vapor phase with air at 440°C. Steam was added and the mixture passed over a vanadium pentoxide-pumice catalyst. The product consisted of a solid fraction of high-molecular weight fatty acids, a water-soluble portion containing the lower fatty acids, aldehydes and ketones, and a liquid cut of unchanged kerosene. The total yield of fatty acids amounted to 7.5 per cent.

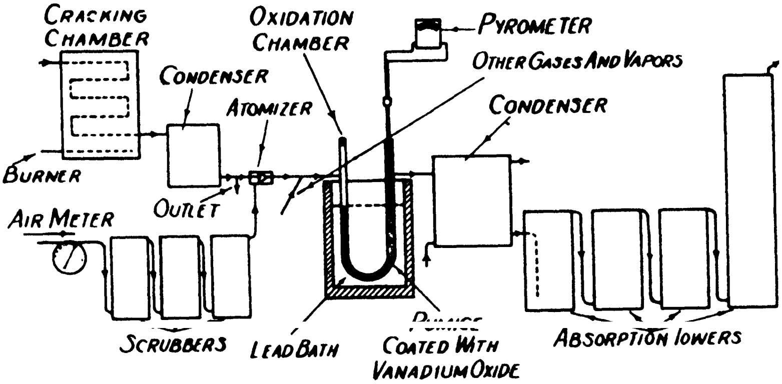

FIG. 216.—Flow Scheme for Partial Oxidation of Cracked Petroleum Distillates. (Carleton Ellis)

Another procedure consists of spraying a mist of cracked petroleum oil, with air, into a reaction zone filled with vanadium oxide catalyst, the temperature being kept below a red heat.[21] As an example, kerosene was introduced into cracking coils heated to 500-600°C. and the vapors then led into air-cooled condensers. The higher-boiling fractions were condensed and the lighter constituents then mixed with air and cooled to room temperature, before entering the reaction chamber, in order to prevent the reaction from becoming too violent. In this way the formation of carbon was retarded. Furthermore, as a result of the cooling prior to oxidation, the products of cracking were partially condensed to a mist. The fine droplets thus formed were not so readily oxidized as material completely in the vapor phase, so that the tendency for excessive oxidation to occur was reduced. The reaction tube, containing vanadium oxide-impregnated pumice, was maintained at 425-450°C. Organic acids, aldehydes and the like were formed. Among the products, phthalic anhydride was identified. Some of these could be converted directly, by use of phenol or resorcinol, into phthalein dyes.

Weber[22] prepared intermediates from petroleum which could be used advantageously in oxidation processes. He subjected a specimen of kerosene to cracking at various temperatures and later oxidized the products with air. The oxidation was accomplished with the aid of a vanadium oxide catalyst mass which was heated in a lead bath at 750°F. James[23] reports that the heat of reaction engendered in the vapor-phase oxidation of petroleum hydrocarbons can be controlled if a series of reaction catalyst-zones is employed, each zone bringing about a fraction of the total oxidation to be carried out. Blue oxides of molybdenum or uranium oxides are suggested as catalysts, and the reaction is to be carried out at a temperature just below red heat. The reaction may be further controlled by the addition of a diluent such as steam or exhaust gases to the mixture of petroleum vapor and air. Mitscherling[24] proposes a photochemical oxidation process for the conversion of hydrocarbons in the vapor or liquid phase. The hydrocarbon material in the vapor phase, for instance, is contacted with a solid catalyst (such as activated charcoal, copper sulphate, carbonate or hydroxide deposited on pumice, or sodium acid sulphite) in the presence of the radiation from a positive-column neon lamp. Cracking processes similar in nature are reported as well. The radiating lamp may contain argon, krypton or other noble gas. The lamp may consume from 180 to 300 watts of electric energy at 12,000 to 15,000 volts.

Nitrogen oxides may also be used as catalysts in the air oxidation of petroleum fractions. Sheely and King[25] treated the vapors of a cleaner's naphtha at 400°C. with air and nitric acid vapors. The acid vapor catalyst was regulated as to its concentration by the temperature of the liquid acid, the pressures of the vapors present ranging from 21 to 68 mm. The products consisted of aldehydes and acids of 8 to 10 carbon atoms. Up to 20 per cent yields of aldehydes were obtainable, while acid yields as high as 90 per cent were reported.

REFINING OF OXIDATION PRODUCTS OF HYDROCARBONS

When petroleum hydrocarbons are oxidized with air, several types of oxygenated derivatives are formed, including carboxylic and hydroxy-carboxylic acids, lactones, estolides[26] (intermolecular esters of hydroxy-carboxylic acids), alcohols, ketones and other oxidized bodies, along with unoxidized hydrocarbons. These products may be separated and refined in several ways. For instance, the crude oxidation products may be subjected to distillation whereby the lower-boiling constituents are separated from those of higher boiling points. The high-molecular-weight acids thus obtained may then be further refined by hydrogenation.[27] In order to effect a separation of saponifiable and unsaponifiable matter, the oxidation product is agitated with lime and then distilled, under conditions such that the calcium salts are not decomposed while the volatile unsaponifiable matter is removed.[28] In the vapor-phase oxidation of petroleum hydrocarbons, certain low-molecular weight acids are formed which remain in the non-condensed gases issuing from the coolers. These gases are sent through scrubbers filled with calcium hydroxide and the volatile acids removed as their calcium salts.[29]

FIG. 217.—Flow Diagram for Production of Acids by Direct Oxidation of Propane. (P. J. Wiezevich and P. K. Frolich) (See Chapter 37.)

Another method for removing oxidized from unoxidized bodies, as well as a separation of oxygenated bodies of various oxygen contents, involves the use of liquid sulphur dioxide.[30] At low temperatures (—45°C.) this liquid dissolves principally the acids present. At somewhat higher temperatures the alcohols and aldehydes are dissolved. At even higher temperatures, but still below the normal boiling point of liquid sulphur dioxide (—8°C.), the latter extracts olefins and aromatic substances. By a careful control of the temperature and the proportion of sulphur dioxide, a fractional extraction can be accomplished.

It has been found that if liquids such as water, benzine, benzene or trichloroethylene are sprayed, in a finely divided form, into the crude acids heated to temperatures between 150° and 300°C., and under pressures of 10 to 50 mm., an almost quantitative separation of fatty acids from hydroxy-carboxylic acids is effected.[31] In this manner, the fatty acids are obtained in the distillate and the hydroxy acids in the still residue. Besides being applicable to mixtures of acids, the above process may also be used in refining crude oxidation products which have received no previous treatment.

In case it is preferred to convert the hydroxy into unsaturated acids, the crude acids are heated to 150-250°C. for several hours in the presence of agents which promote dehydration, such as mineral acids, sulphonic acids or zinc chloride.[32] The heating may be carried on in an atmosphere of hydrogen or carbon dioxide. By this treatment the solubility of the acids in petroleum ether, and their iodine numbers, are increased. At the same time the tendency for pitch-formation during subsequent distillation is greatly diminished. As an example, 500 parts of the product obtained by oxidizing gas oil at 150°C. with air, are treated for 4 hours at 250°C. under a pressure of 50 atmospheres with hydrogen and finely-divided nickel, in the presence of 5 parts of naphthalene monosulphonic acid. Lighter-colored acidic bodies (480 parts) are obtained. The two materials show the following differences:

	Solubility in Petroleum Ether	Iodine Number	Pitch Obtained on Distillation
Initial material. . . .	58.2%	17.8	20%
Treated material.	91.8%	46.7	3%

The crude acids, obtained from oxidized petroleum by any of the above methods, may be further separated into high- and low-molecular weight acids by treating their alkali salts with calcium hypochlorite. The calcium salts of the low-molecular weight acids are removed by washing with water, the salts of the high-molecular weight acids remaining undissolved.[33]

USES OF OXIDATION PRODUCTS OF PETROLEUM

Top oils, which reduce the breaking-in time of internal combustion engines and diminish carbon accumulation, are made from certain of the oxidation products of petroleum. These top oils are added to the fuels used in such engines and tend not only to furnish extra lubrication for the valves and pistons but also to soften carbon deposits. As an example, 3 per cent of an oxidized fraction of Pennsylvania petroleum oil is added to 97 per cent of unoxidized paraffin oil, and 1 volume of the mixture is added to 200 volumes of the fuel. The oxidized oil employed for this purpose contains esters, alcohols and ketones, and is neutral in character. Compositions containing these neutral oxidation products are also blended with crankcase lubricants.[34]

Lubricating oils may be incorporated in the soaps formed from the oxidation products of aliphatic petroleum hydrocarbons. The solid or semi-solid compositions thus prepared are proposed as lubricating greases. Or, the free acids, of average molecular weight of 160 to 165, may be dissolved in petroleum distillates to give oils possessing marked penetrating qualities.[35]

The alkali salts of monocarboxylic acids have also been suggested for use in the preparation of certain liquid dispersions such as insecticidal and fungicidal plant-sprays, presumably of the insecticide-in-water type. On the other hand, the free acids have been employed in breaking emulsions of the water-in-oil type.[36] The products formed by chlorinating these acids have also been used for the latter purpose.[37]

The water-insoluble, petroleum-soluble saturated monocarboxylic acids (containing up to 12 carbon atoms) prepared from petroleum are said to act as activating materials in rubber vulcanization.[38] Acids obtained from paraffin oil can be condensed with phenol and formaldehyde or furfural to produce plastic compounds.[39] The polycarboxylic acids which are formed from petroleum can be condensed with polyhydric alcohols to produce resinous bodies also.[40]

Chapter 43

Oxidation of Paraffin Wax

As the multitude of publications bear witness, much work has been done on the oxidation of paraffin wax and related substances with air and oxygen, as well as with other oxidizing agents. These reactions can be controlled so as to furnish predominantly either alcohols or acids or other oxygen-containing bodies. In spite of the fact that these various types of oxygenated compounds have been made, there still exists some doubt as to the exact structures of the hydrocarbons comprising paraffin wax.

The acidic materials resulting from the oxidation of high molecular weight paraffins have been utilized principally for the manufacture of soaps. Other products, such as esters, have been employed as beeswax substitutes and in miscellaneous preparations (Chapter 45). Although fat-like bodies have been obtained by the oxidation of paraffins[1] and by esterification of the higher aliphatic alcohols with acids of petroleum origin,[2] nevertheless it is questionable from an economic viewpoint whether the manufacture of synthetic fats from petroleum could compete with natural fats, except possibly in times of extreme emergency.[3] For instance, during the World War, German soldiers were fed 6000 tons of synthetic fats made by esterifying ethyl alcohol with the acids formed by the ozonolysis and subsequent heating of unsaturated hydrocarbons resulting from the low-temperature distillation of coal.[4]

Because of the complexity of the oxidation products of paraffin wax and the uncertainty of the nature of its components, the term "wax acids" seems best suited for the acids produced therefrom.

OXIDATION WITH AIR

For the production of wax acids, oxidation of paraffin wax with air appears to be the most economical.[5] Temperatures employed generally ranged from 150° to 180°C., though higher temperatures can be used. Under the latter conditions more vigorous oxidation occurs, accompanied by larger yields of lower molecular weight, or more volatile, products. The application of increased pressures often aids in speeding up the reaction. The velocity of reaction is affected also by the grade of feedstock being treated. For example, Reiner[6] reported that paraffin wax (m.p. 52.5°C.) was more rapidly converted (by air) to acids than ceresin wax (m.p. 56°C.), and that in both instances the change was faster at 140°C. than at 120°C. It has been proposed to refine the hydrocarbons with sulphuric acid and a small proportion of oxides of nitrogen prior to oxidation.[7] Refining conditions, however, should be sufficiently mild to avoid the occurrence of objectionable reactions with the hydrocarbons.

Orlov and Tishchenko[8] noted the formation of volatile acids, aldehydic bodies and a considerable proportion of an asphaltic mass during treatment of paraffin wax (m.p. 57°C.) at 120-140°C. with air. On further oxidation with air (by weathering) the asphalt yielded substances which closely resembled natural humic acids. The development of dark-colored, resinous materials may be avoided by continuously withdrawing the partially oxidized wax and adding fresh wax to the reaction zone.[9] At a lower temperature (52°C.), other investigators obtained both fatty and hydroxy acids as well as their anhydrides, lactones, and lactides.[10] Hydroxy acids corresponding in composition to $C_{13\text{-}17}H_{26\text{-}34}(OH)COOH$ and one whose formula was believed to be $C_{35}H_{69}(OH)COOH$ were identified. The latter acid, whose lactone melted at 58-59.4°C., was prepared by hydrolysis of its methyl ester (m.p. 46-48°C.).

Varlamov[11] found that the employment of catalysts, manganese, nickel, chromium, and cobalt, resulted in higher yields of acids but the proportion of hydroxy acids was also increased. The alkali carbonates were found to be negative catalysts.

Friedolsheim and Luther suggest treatment of paraffin wax at 120° to 180°C. with air in the presence of alkalies such as sodium hydroxide or carbonate.[12] A small proportion of manganese naphthenate or zinc stearate may be added. Under these conditions 70 per cent of the wax is said to be converted into acids. Other metallic catalysts which have been used in the liquid-phase oxidation of paraffin wax include calcium, barium, and magnesium naphthenates,[13] and heavy-metal cinnamates,[14] carbonyls, carbides or palmitates,[15] and stearates.[16]

Burwell[17] investigated the oxidation of saturated petroleum hydrocarbons, with air and oxygen, under various pressures and at temperatures below the cracking temperatures of the hydrocarbons. The air-oxidations were carried out under about 15 to 40 atmospheres pressure and at 120° to 180°C., usually, however, below 160°C. Manganese oleate or unsaponifiable, partially oxidized hydrocarbons were used as catalysts. Paraffin wax melting at 122° to 124°F. and averaging twenty-four carbon atoms gave acids corresponding to an average of twelve to fourteen carbon atoms. By using large quantities of initial hydrocarbons (200 pounds), it was possible to isolate and identify many of the low-boiling volatile acids formed. Among those identified were formic, acetic, propionic, butyric and valeric and others up to 10-carbon acids. In the wash waters were found lactic, and succinic and other dibasic acids. Alcohols, ketones, lactones and esters were also formed. The proportion of the latter, in some cases, was believed to represent a large part of the oxidation products. By use of charges of not less than 1000 pounds of wax many products of commercial utility were obtained.[18]

From this work it was noted that those materials containing a high percentage of straight-chain hydrocarbons oxidized readily but that other specimens, low in these compounds, required catalysts. From the products formed it was concluded that the principal reaction involved the beta-carbon atom rather than the primary and that the second preference was for the gamma-carbon atom, and so on toward the center of the molecule. It is interesting to note, however, that at higher temperatures (cracking temperatures) the alpha-carbon atom is more susceptible to oxidation than is the beta, the initial products being aldehydes.[19]

Yukhnovskii and Rokhlin,[20] studying the oxidation of petrolatum, found calcium naphthenate to be a better catalyst than magnesium naphthenate. By carrying out their oxidations under 3 to 4 atmospheres pressure they could reduce the reaction time by as much as 500 per cent and considerably lessen the air consumption. The optimum reaction temperature was 110-115°C. At higher temperatures more gasoline-insoluble material was formed. At higher pressures the proportion of hydroxy acids was increased without an increase in the total yield of acids. On the other hand, 160°C. has been reported as the optimum temperature for the air-oxidation of paraffin wax under atmospheric pressure.[21] However, Davanakov and Fedotova[22] report that the catalytic action of the ordinary metallic soaps is effective only at the lower temperatures (i.e., 120 to 140°C. but not at 160°C.). The catalysts used by these investigators were prepared by the interaction of salts of the metals used (manganese, calcium, aluminum) with the fatty acids of paraffin oxidation at 160°C. The calcium catalysts were more effective than the aluminum, and the manganese still more active. In semi-commercial experiments, it was found that the manganese catalysts increased the rate of reaction at 120°C. by a factor of ten. At 140°C., the reaction in the presence of this catalyst left only 15 per cent of unsaponifiable matter. Davanakov[23] reports, further, that the influence of catalysts is increased not only by lower temperatures, but also by the use of less highly refined paraffin.

Berlin and Kuznetzova[24] subjected samples of foots oil, containing various proportions of paraffin wax, to oxidation with air at 160-170°C., both in the presence and absence of naphthenate catalysts. When dealing with oils of high wax content (above 85 per cent) they found that the oxidation proceeded smoothly without catalysts, whereas, oils of lower wax content needed catalysts in order to produce satisfactory yields of oxidation products. It has been suggested that the oil content of petrolatum or slop wax be reduced by extraction with low-boiling hydrocarbons, e.g., propane or butane, admixed with non-solvents for wax, such as alcohols, ketones or chlorinated hydrocarbons.[25] After distillation, the wax may be subjected, in the liquid phase, to oxidation with air. In an attempt to elucidate the function of catalysts in these air oxidations of paraffin waxes, Plisov[26] studied the formation of peroxides and acids during the reaction, both when catalysts (sodium and calcium salts of naphthenic and higher fatty acids) were present, and in their absence. It was found that when catalysts were not present, the amount of peroxides formed increased slowly at first, then rapidly, to a maximum value reached in about 3 hours, and then decreased. After 5 to 6 hours, no peroxides could be detected. In the presence of catalysts, the concentration of peroxides did not pass through a maximum, but declined steadily to zero after 4 to 5 hours.

In some cases it is desirable to restrain the extent of oxidation and thus to obtain considerable amounts of aldehydes and alcohols rather than acids. This has been accomplished by oxidizing paraffin wax in the presence of orthoboric and acetic acids.[27] Under these conditions the products are found to contain relatively large proportions of alcohols as their boric acid esters, in which form they are apparently protected against further oxidation. The esters are separated from unreacted paraffin by extraction with ethyl alcohol. After evaporation of the solvent, the residue of wax-alcohol borates is repeatedly extracted with boiling water until hydrolysis is complete and all boric acid removed. A mixture of crude alcohols, prepared in this manner from hard paraffin wax, had the following characteristics:

Crude Wax Alcohols

Melting point	34°C.
Acid number	11
Ester number	27
Saponification number	38
Acetyl number	198
Ash	0.01%

By saponifying, extracting the soap solution with ether, and evaporation of the latter, the crude alcohols were freed of fatty acids. The refined alcohols then exhibited the following properties:

Refined Wax Alcohols

Specific gravity (50°C.)	0.860
Melting point	31.5°C.
Acid number	0.9
Ester number	6.5
Saponification number	7.4
Hydroxyl number	165

Arsenious or phosphorous acid may be used as the oxidation catalyst in place of boric acid.

Several means have been employed for lowering the air-consumption of these oxidation operations, as for instance, by effecting reaction under increased pressures.[28] Another procedure consists of lengthening the period of contact between the air and hydrocarbon.

Friedolsheim and Luther[29] passed molten paraffin wax and air concurrently through a multiple-section heated tower (See Fig. 218.) Among advantages of this method of oxidizing wax is that the partially oxidized hydrocarbons are carried along in contact with air of decreasing oxygen content, thereby diminishing the tendency for excessive oxidation reaction to occur. Diluent gases may also be used to serve the latter purpose. In other instances the reactants are conducted through filler bodies[30] in order that they may become more intimately mixed. Various other methods, such as spraying the liquid hydrocarbons into the top of the reaction vessel and air through the bottom, and the use of high-speed stirrers, have been suggested.[31]

USE OF OTHER OXIDIZING AGENTS

In place of air, the oxides of nitrogen (particularly nitrogen dioxide), nitric acid, potassium permanganate, and ozone have been used for the oxidation of paraffin wax.[32] Electrochemical methods may be employed also, though reaction appears to be much slower and in some instances the products are contaminated with a substantial proportion of unsaponifiable material and resins which are difficult to eliminate.

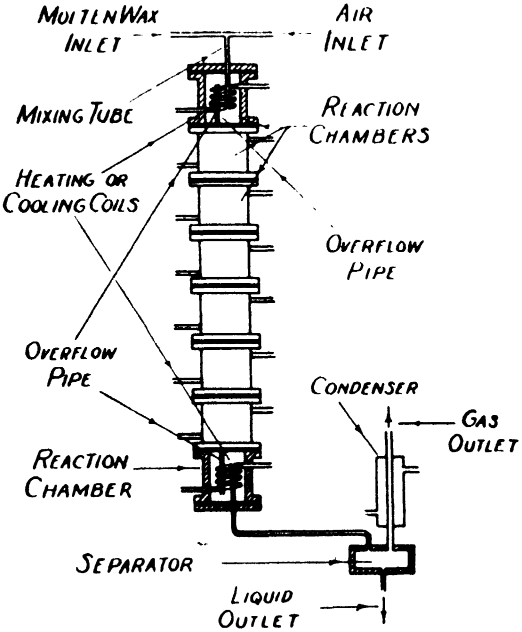

FIG. 218. Tower of Chambers for Paraffin Wax Oxidation. (A. v. Friedolsheim and M. Luther)

Beck and Diekmann[33] point out that higher yields of acids are obtainable if reaction of paraffin wax and aqueous nitric acid is carried out under pressure, or if nitrogen dioxide is passed into the reaction mixture. It was their belief that nitrogen dioxide, not nitric acid, was the principal oxidizing agent and that by maintaining a high concentration of this dioxide oxidation was accelerated. As an example, paraffin wax melting at 52°C. was oxidized in a chrome-nickel-steel tower at 80°C. and under 4 atmospheres pressure with 50 per cent nitric acid. The acid, in a finely divided state, was allowed to trickle through the molten wax while nitrogen dioxide (NO_2) was blown in at the bottom of the tower. By releasing the pressure, nitric oxide (NO) escaped from the top. The final oxidation product, which possessed an acid number of 210 and a saponification number of 290, contained 3 per cent by weight of nitrogen and 15 per cent by weight of unoxidized hydrocarbon. By saponification the nitrogen compounds and unreacted paraffin were removed. The wax acids were then further purified by distillation.

Carboxylic acids, particularly those having an acid value greater than 400 and prepared by the oxidation of paraffin wax with nitric acid or oxides of nitrogen, may be esterified with monohydroxy alcohols or phenols to furnish softening and gelatinizing agents.[34] Partial esterification of polyhydroxy alcohols, or their ethers, gives the same type of products. These may be incorporated in lacquers, films and plastics (e.g., nitrocellulose or various synthetic resins) to impart plasticizing or softening action.

MISCELLANEOUS OXIDATION REACTIONS

Sapropels[35] can be oxidized with nitric acid to give 30-60 per cent yields of oxidation products which consist of carboxylic acids and their saponifiable derivatives. The acids are of high molecular weights, low in hydrogen and iodine numbers and soluble in petroleum ether. The last-named property apparently indicates only a small proportion of hydroxy acids.

Zherdeva and associates[36] investigated the oxidation of ceresins (m.p. 85-90°C.) from Grozny, Surakhany and Turkmenia. The specimens were blown with air at 160-170°C. for 6 hours. Gasoline-soluble acids were obtained in 30-48 per cent yields, along with 3.7-12 per cent of hydroxy acids. The gasoline-soluble portions had acid numbers of 107-151, saponification numbers of 137-192, and melting points of 41-72.5°C.

SEPARATION OF OXIDIZED FROM UNOXIDIZED MATERIALS

This separation can be accomplished by several means. For example, the oxidation products may be heated, under pressure, with alkalies to above 200°C. in the presence of hydrogen.[37] The hydrogen may be evolved from suitable substances added to the alkali. It is also advantageous to add hydrogenation catalysts to the mixture since some water is likely to be split off the hydroxy acids giving unsaturated acids. The unsaponifiable matter is then removed by extraction with methyl alcohol, isopropyl alcohol, or benzine.[38] Instead of alkali hydroxides, in some cases, the alkaline earth hydroxides, as aqueous suspensions, may be used.[39] In order to convert even the lactones, esters, estolides and lactides to their alkali metal salts, oxidized paraffin is heated, in an autoclave, with 20 per cent alkali carbonate, at temperatures ranging from 60°C. to 300°C. and under pressures of 1 to

15 atmospheres.[40] Or, the procedure may be reversed, whereby the oxidized wax is dissolved in an inert organic solvent, such as diethyl ether or benzine, and the resulting solution then extracted with an aqueous solution of an alkali or organic base which dissolves the saponifiable material.[41] The aqueous layer is separated and extracted with fresh portions of organic solvent. The soaps are then recovered by the evaporation of their aqueous solutions or the wax acids are liberated by acidification of the soap solutions by means of mineral acids. One method consists of introducing dilute nitric acid into the bottom of a tank containing a soap solution so that the organic acids formed may float to the surface where they are protected from further contact with the incoming acid.[42] Carrier and Reeves[43] report a separation of the saponifiable from the unsaponifiable constituents of a mixture resulting from the oxidation of wax, using ammonia and solvent extraction. Saponification with ammonia is carried out under pressure (80 pounds per square inch) at 140 to 150°C. in the presence of water and alcohol (e.g., isopropanol), for two hours. The resultant mixture is then extracted with gasoline, to remove the unsaponifiable matter. The aqueous alcohol solution contains the saponified matter, and this solution is steam distilled to drive off ammonia, water and the alcohol. The residue is treated with sulphuric acid to free the fatty acids and hydrolyze any acid amides which have been formed, and the fatty acids separated from the resulting aqueous solution. An analogous process has been suggested by Beller and Schellmann,[44] who employ an alkali or alkaline earth metal in the saponification step, in the form of an oxide, hydroxide or carbonate.

In order to produce wax acids free from hydroxy acids, oxidized wax is heated, under pressure and above 200°C., in the presence of alkaline substances such as sodium or calcium hydroxide and in an atmosphere of hydrogen. Water is split off during the reaction giving the salts of unsaturated acids.[45] Harder[46] suggests that a similar result may be attained by treating the mixed products of oxidation of a wax with an alkali such as sodium hydroxide and water, together with an agent which will release hydrogen in alkaline media (e.g., zinc dust) at a temperature above 260°C. Ittner[47] suggests employing reduced pressures and temperatures above 250°C. Simultaneously, the mixture is blown with steam, carbon dioxide, or the vapors of toluol or xylol. Oxidation products of petroleum which possess disagreeable odors and which give soaps of poor lathering properties, are, by the above treatment, converted into almost odorless acids which furnish soaps of desirable sudsing properties. Soaps made from the acids thus obtained are also more easily salted out than are the original hydroxy-acid soaps and when blended with higher-grade laundry soaps, may be used in larger proportions without producing soaps which are undesirably soft. Another procedure for dehydrating hydroxy acids consists of heating the calcium soaps in benzene, at 250° to 292°C., using an autoclave. In this manner the hydroxy-acid salts lose water to give the corresponding unsaturated compounds.[48] If the acids thus produced are of objectionable color, they may be dissolved in naphtha and treated with concentrated sulphuric acid, followed by active clay. This results in acids of improved color.[49]

On the other hand, the oxidized and unoxidized portions can be separated by selective solvents. Peukert[50] extracted oxidized paraffin wax with ten parts of methyl alcohol in the cold and in this manner removed the greater part of the oxidized material. He also found pyridine to be a useful extraction medium. Beck and associates[51] purified aqueous crude wax-acid soaps by heating them to the melting points of the corresponding anhydrous soaps and then removing the volatile constituents by reducing the pressure. This treatment gave the anhydrous soaps which were almost free of volatile substances of high boiling points. The soaps were then removed in this form or were redissolved in water to give solutions of the desired strength. Pungs and Behringer[52] separated high-molecular weight alcohols from high-molecular weight acids by fractionally distilling mixtures of these under reduced pressures with the aid of steam or the vapor of an organic liquid such as ethyl alcohol or benzene. These mixtures include natural waxes and oxidation products of paraffins. For example, crude montan wax is treated with superheated steam at 200°C. under 60 mm. pressure. The esters present are split up and during a period of 5 hours 20 per cent of the original material distils over and is collected as a slightly yellow solid melting at 78° to 79°C. This is composed of high-molecular weight alcohols having an acetyl number of 120.

The removal of oxidized from unoxidized products of paraffin wax has also been effected by means of liquid sulphur dioxide, acetic acid, ammonia, and other substances.[53] Vesterdal[54] observed that the hydroxy acids could be separated from the fatty acids produced in wax oxidation by the use of phosphoric acid. This investigator states that if concentrated phosphoric acid is agitated with a considerably greater volume of the crude acids, and allowed to stand, separation takes place. The phosphoric acid and hydroxy acids form a lower layer, while the fatty acids form a second layer which may be separated.

STRUCTURE OF WAX ACIDS

As yet, the exact steps occurring in the oxidation of paraffin wax or the structure of the acids thereby obtained are not clearly understood. This is probably due, in large part, to the fact that considerable disagreement exists as to the exact structures of the hydrocarbons comprising the wax. For instance, Marcusson[55] concluded that ordinary paraffin wax consists only of normal aliphatic hydrocarbons, whereas Gränacher[56] expressed a belief that it contains principally branched-chain hydrocarbons. On the other hand, by successive crystallizations of petroleum asphalt from pyridine and ether, and finally from benzene, Müller and Pilat[57] separated the bulk of the paraffin wax into four fractions which contained both true paraffins and some cyclic hydrocarbons. X-Ray studies[58] on white paraffin wax have indicated the presence of saturated cycloparaffins and branched-chain paraffins.

Shoruigin and Kreshkov[59] separated hydroxy acids from oxidized paraffin wax by precipitation of their cadmium salts. From these they isolated both straight- and branched-chain acids. By treatment with dimethyl sulphate the carboxylic, but not hydroxyl, groups were methylated. Lactonization of a portion of the acids readily occurred. Distillation of the mixed methyl esters effected an increase in the iodine number, thus indicating that some β-hydroxy acids were present. The formulas of the acids isolated corresponded to either $C_nHH_{2n}O_3$ or $C_nH_{2n+2}O_3$, in which n varied from 10 to 32. Comparison of melting points of these acids with those of known structure indicated the former were either highly branched or mixtures of closely related isomers.

Other investigators, however, have reported that oxidation of paraffin wax leads to the formation of fatty acids such as isopalmitic or arachidic, or of acids having an uneven number of carbon atoms.[60]

USES OF WAX ACIDS

As previously mentioned, the largest use is probably in the manufacture of soaps. Such materials exhibit not only detergent properties but also those of emulsifying agents. In the latter capacity they are reported to be more effective than green soap in the preparation of insecticides from petroleum fractions, such as kerosene or gas oil.[61] Ellis[62] has proposed to employ wax acids for making soap powders. One method is to mix the acids with a relatively large quantity of solid alkali, e.g., sodium carbonate, and heat the mixture. Either liquid or solid fractions of the acids, obtained by filtration at any desired temperature or by fractional distillation, may serve as the acidic constituents of the products. The wax acid soaps are said to produce solutions of high foam-forming and washing capacity.[63] The ammonium soaps of the wax acids in particular are recommended as agents in bringing about the separation of oil-water emulsions, although it is said the raw acids or other salts may be employed for this purpose.[64] A semi-fluid detergent reported to be particularly applicable for removing grease and oil has been prepared by dissolving potassium soaps of wax acids in hydronaphtha.[64a] The proportion of soap may vary between 1 per cent and 50 per cent, depending upon the consistency desired in the detergent.

Oxidized paraffin wax may be compounded with lubricating oils, and the acidity of the resulting material reduced by treatment at 120-140°F. with a decolorizing clay.[65] Addition of esters, for example, those from wax acids and isopropyl alcohol, to lubricating oils renders the latter particularly adaptable during the "running in" period of motors.[66] Incorporation of various salts of these acids, such as those of zinc or magnesium[67] and also of lead[68] with lubricants has been suggested. Barth and Corlew[69] state that the wax acids of molecular weight near 400, acid number of 120 or higher may be converted to pour point depressants for use with lubricating oil. The acids are saponified with a five per cent aqueous solution of sodium hydroxide, and the aqueous solution of soaps decanted from unsaponifiable matter. To the soap solution, a slight excess of aluminum nitrate is added, and the resulting insoluble aluminum soaps are then coagulated by heating (to 190°C.). The resulting soaps are washed with water and benzol, and the purified product added to lubricating oil.

A small proportion of alcohols having 8 or more carbon atoms, and derivable from the oxidation products of paraffin wax are of aid in preventing foam in fermentation processes, it has been reported.[70] These alcohols are said to be useful in the preparation of yeast cultures.

The high-molecular weight acids produced by these oxidation processes are said to be useful in making a wave-breaking oil. A mineral oil of low wax content is mixed with high molecular weight organic acids, and the resultant mixture may be used.[71]

Frolich[72] has proposed that the high molecular weight oxygenated products resulting from the oxidation of wax may be cracked to produce lower oxygenated products. Thus, the oxygenated wax products are cracked in the vapor phase at a temperature of 400° to 700°C. in contact with calcium carbonate or ferrous oxide. If temperatures of 600°C. are employed, a contact time of one second is recommended. The high-molecular weight compounds are split in this way to yield a mixture of higher ketones, aldehydes, unsaturated hydrocarbons, pyrones and other oxygenated compounds of lower molecular weight than the feed stock.

Ralston, Pool and Harwood[73] report that wax acids may be reacted with ammonia to form the corresponding aliphatic nitriles. The acids are heated to a temperature somewhat below the boiling point (e.g., about 300°C.) and gaseous ammonia is passed in. The conditions are such that water formed by the reaction is continuously allowed to escape. The course of the reaction, it is suggested, is a primary formation of the ammonium soaps of the acids, followed by a rearrangement with loss of a molecule of water to form an amide. If the water is not permitted to escape, the reaction reaches an equilibrium at this step. However, if a great excess of ammonia is continuously blown through the liquid acids, the water is carried off. The ammonia is recycled, and the water is separated at each cycling. Although the fatty acids tend to decompose at temperatures in the range of 300°C., the investigators report, the presence of the excess of ammonia appears to inhibit this, and the reaction proceeds to give good yields of the nitriles.

Chapter 44

Oxidation from the Standpoint of Detonation

There are two limits of inflammability for each pair of gases (combustible gas and supporter of combustion) forming a combustible mixture. The lower limit corresponds with the minimum proportion and the upper with the maximum proportion of combustible gas conferring inflammability on the mixture. Factors which affect these limits include direction of propagation of the flame, dimensions of the containing vessel and its open or closed condition, turbulence of the gases, and great variations in pressure.[1]

LIMITS OF INFLAMMABILITY OF GASEOUS MIXTURES

Jones, Yant, Miller and Kennedy[2] have determined the limits of inflammability of diethyl ether and ethylene in air and oxygen. For measurement of air mixtures, an upright closed iron cylinder (10.2 x 96.5 cm.) was used. For determinations in an atmosphere of oxygen a glass tube (4.4 x 60 cm.) was employed. The mixtures were ignited by a spark from an induction coil and the flame propagated upward through the tube or cylinder. The values observed for the upper and lower limits of inflammability of diethyl ether in air were 36.50 and 1.85 per cent by volume respectively. The same limits for ethylene-air mixtures were found to be 28.60 and 2.75 per cent by volume respectively. The explosion range of such mixtures as those of carbon disulphide, carbon tetrachloride and air have been determined by Popov and Bezzub.[3] The lower ignition limit for a mixture of air and pure carbon disulphide was found to be 1.7-1.8 per cent, and for a commercial product (79.4 per cent pure) it was 1.19 to 2.1 per cent.

Effect of Pressure. Breton and Laffitte,[4] in measuring the limits and speed of detonation for mixtures of oxygen with propane, butane, acetylene, ammonia and diethyl ether, observed that with increase of pressure the explosive limits were widened. Thus, lower and upper limits of 15 and 90-90.4 per cent by volume were found for hydrogen under 1 atmosphere. With a pressure of 8.7 atmospheres the lower and upper limits were 13.9-14.3 and 91.1-91.3, respectively. It was also noted that the addition of small quantities of hydrogen to a carbon monoxide-oxygen mixture lowered its lower explosion limit and that lead tetraethyl had no appreciable effect on the detonation limits.

Effect of Temperature. The inflammability limits of mixtures of air with isopentane, hexane, heptane, octane, benzene, toluene, cyclohexane and cyclohexene, methanol, ethanol, propanol, acetone, as well as blends of these over the temperature range 100° to 300°C. have been investigated.[5] In the temperature interval 100-250°C. the upper and lower limits for benzene were found to be 17.9 and 4.9 per cent, respectively, while for toluene they were 27.0 and 3.0 per cent. The lower limit of inflammation was linear with reference to temperature for both hydrocarbons. The upper limit, on the other hand, for benzene obeyed the same law, but above 200°C. the values for toluene were distinctly lower than would correspond to linear variation. This was explained by the formation of an oxidation product in the case of toluene, which with the unoxidized aromatic gave rise to a mixture having an upper limit lower than that of pure toluene. Although the lower limits as determined for cyclohexane and cyclohexene were close together, the difference in the upper limits was more marked. At 150°C., a mixture of air and ethanol containing 80.5 per cent water vapor still propagated flame.

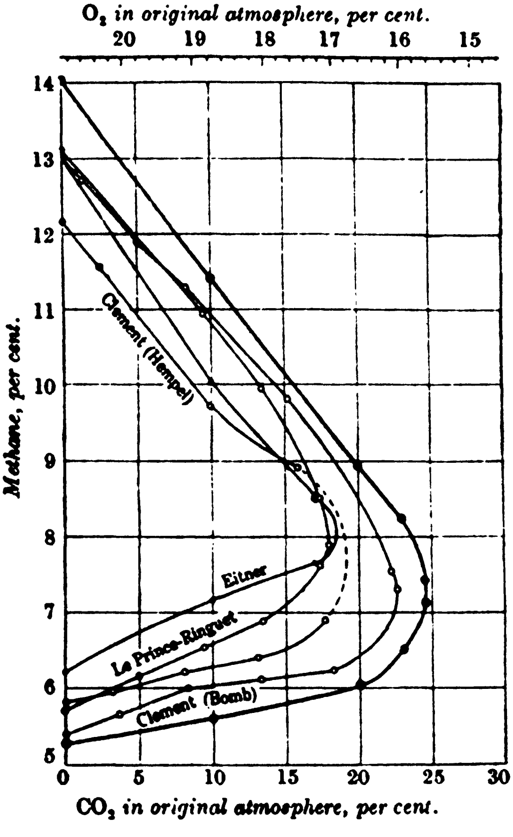

FIG. 219.
Influence of Carbon Dioxide on Inflammability Limits of Methane-Air Mixtures. (H. F. Coward and F. J. Hartwell)

Courtesy Journal of the Chemical Society

In 1891, Le Chatelier stated that a mixture of any two limit mixtures (both upper or both lower) will itself be a limit mixture. Briand[6] tested this rule upon binary and ternary vapor-air mixtures, namely ethanol and cyclohexane, ethanol-benzene, benzene and cyclohexene, ethanol-methanol-benzene, and ethanol-benzene-cyclohexane. Although only the lower limit concentrations of these mixtures were determined, the accord between the calculated and found values was good.

FIG. 220.—Effect of Nitrogen on Inflammability Limits of Methane-Air Mixtures. (H. F. Coward and F. J. Hartwell)

Effect of Flame Propagation. The effect of the direction of flame propagation on the limits of inflammability of hydrogen and deuterium is discussed by Payman and Titman.[7] The lower limits for both hydrogen and deuterium in air and oxygen (with a tube 2.2 x 45 cm.), using upward propagation of flame, were 3.9 and 4.9 per cent, respectively. With downward propagation under the same conditions the lower limits were found to be 9.1 and 10.2 per cent for hydrogen and deuterium, respectively. However, the upper limits were the same irrespective of the direction of propagation of flame, being 94.2 and 73.0 per cent for hydrogen in oxygen and air, respectively. Values for deuterium were 94.7 per cent with oxygen and 75.0 per cent with air.

Effect of Inert Gases. The influence of inert gases on the extinction of methane flames has been investigated by Coward and Hartwell.[8] In methane-air mixtures, carbon dioxide narrowed the limits of inflammability as the proportion of diluent was increased. This is shown graphically in Fig. 219. The heavy curve represents the limits (upper and lower) of inflammability of methane in atmospheres composed of air admixed with the indicated proportions of carbon dioxide. As the amount of diluent gas is increased, the limits narrow until they meet when the atmosphere contains somewhat less than 25 per cent of carbon dioxide. The increase in the lower limit was attributed to the greater thermal capacity of the carbon dioxide, and this cause, together with the reduction in oxygen content of the atmosphere were considered responsible for the decrease in the upper limit.

FIG. 221.—Influence of Inert Gases on Inflammability Limits of Methane-Air Mixtures. (H. F. Coward and F. J. Hartwell)

---

[8] H. F. Coward and F. J. Hartwell, *J.C.S.*, **1926**, 1522; *Chem. Abs.*, 1926, **20**, 3573; *Brit. Chem. Abs.* **A**, 1926, 805. See also G. W. Jones and R. E. Kennedy, *Ind. Eng. Chem.*, 1935, **27**, 1344; *Chem. Abs.*, 1936, **30**, 289; *Brit. Chem. Abs.* **B**, 1936, 177; *J. Inst. Pet. Tech.*, 1936, **22**, 22A.

In the same graph are indicated the results obtained by Eitner,[9] Clement,[10] and Leprince-Ringuet.[11] These results are not strictly comparable, however, for the experimental conditions were somewhat different in each case.

In Fig. 220 the heavy curve represents (as above) the inflammability limits of methane in atmospheres composed of air admixed with the indicated amounts of nitrogen. This figure also includes some values reported by Clement,[12] Leprince-Ringuet,[13] and Burgess and Wheeler.[14] As in the case of carbon dioxide, these data are not strictly comparable, due to differences in experimental procedure. The influence of argon and helium on the limits of inflammability of methane-air mixtures was also investigated. It was concluded that in the methane-air-argon mixtures the lower limit of methane will have smaller values, since argon has a lower heat capacity than air. These facts are indicated by the data shown graphically in Fig. 221. Since the heat capacity of helium is very nearly equal to that of argon, it was thought that these gases should be somewhat alike in their effect as diluents. Fig. 221 shows helium to be markedly more extinctive of methane-air flames than argon. In summarizing the results of the above work, it was stated that the diluent gases affect the inflammability limits of methane-air mixtures by reducing the oxygen content of the mixture, its thermal capacity or its thermal conductivity. The thermal capacity effect is marked in the case of argon, for the lower limit of methane, under conditions described, is reduced from 5.24 per cent in air to 4.40 per cent in an atmosphere composed of 47 per cent of argon and 53 per cent of air.

Jones and Kennedy[15] made a study of the effect of varying proportions of nitrogen and carbon dioxide on the inflammability limits of mixtures of methane, ethane, propane, and butane. Some of the results are given in Table 193. Fig. 222 represents graphically the influence of these inert gases on the values for propane. As the proportion of carbon dioxide increases both limits are raised until they narrow and meet when a ratio of diluent to hydrocarbon of about 8 to 1 is reached. Like-

wise, when nitrogen is employed the limits meet when a ratio of nearly 15 to 1 is attained. Behavior of the inert gases in the case of butane is similarly shown in Fig. 223.

Van Heiningen[16] concluded that the extinguishing action of inert gases decreases in the order: carbon dioxide, helium, nitrogen and argon, regardless of the nature of the explosive gas. Also that the upper explosion limits are mainly affected but the lower ones are little changed by the nature or amount of diluent added.

The influence of inorganic dusts on binary mixtures of air with various combustible gases was investigated by Thompson.[17] The presence of magnesium oxide dust narrowed the explosion range at both ends. With ethylene mixtures this effect was more marked than with those of hydrogen or carbon monoxide. In the case of benzene and diethyl ether the effect was barely perceptible and with methane it was absent. Substitution of silica dust for magnesium oxide dust gave comparable results. With iron carbonyl vapor it was noted that a greater displacement (of explosion range) was effected than with magnesium oxide, but whether the effects were due to the undecomposed carbonyl molecules or to the iron (or oxide) formed by their decomposition was uncertain. An explanation proposed for the action of mineral dusts was that radicals or atoms, i.e., hydroxyl radicals or hydrogen atoms, propagating the reaction chains were absorbed and converted into stable molecules.

FIG. 222.—Effect of Nitrogen and of Carbon Dioxide on Inflammability Limits of Propane. (G. W. Jones and R. E. Kennedy)

Jones and Kennedy[18] determined the amount of carbon tetrachloride that must be added to pentane, hexane, heptane, octane, or gasoline to render the resulting mixtures non-flammable. Determinations of the inflammability limits of such liquid blends were complicated by the differences in boiling points and vapor pressures of the chlorinated compound and the hydrocarbons. Under conditions of complete vaporization in an explosion tube the following percentages of tetrachloride were required to prevent flame propagation: pentane, 66.7; hexane, 70; heptane, 70; octane, 66.7; naphtha (boiling range 97-155°C.) 70; and gasoline (boiling range 31-205°C.) 58.0.

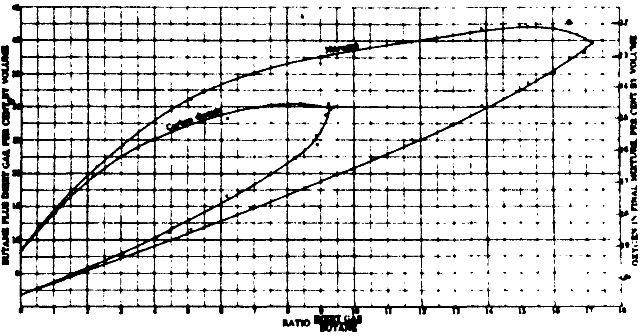
Ignition of Gases by Heated Surfaces

The exposure of inflammable mixtures to heated surfaces has been one of the most popular methods of determining ignition temperatures. The results thus obtained do not give absolute values since they are influenced by other factors, e.g., the nature and extent of the igniting surface.[19] Investigations carried out on the effect of different types of surfaces on the lower explosion limits of methane-oxygen mixtures,[20] revealed that when a quartz vessel, whose surface had been treated with hydrofluoric acid, was used in the temperature range of 602° to 642°C. the induction period of the explosion was reduced to about 3 minutes. Extent of acid treatment of the vessel surface affected the lower limit pressure of the gas mixtures. Thus, the value was 33.5 to 38.5 mm. after a 20 minute treatment and 18.0 to 22.0 mm. when the vessel had been exposed 150 minutes. The age of the surface treated also influenced the results.



Courtesy U. S. Bureau of Mines

Fig. 223.—Influence of Nitrogen and of Carbon Dioxide on Inflammability Limits of Butane. (G. W. Jones and R. E. Kennedy)

Other types of surface treatments studied were the deposition of a silver mirror on the inside of the vessel, the quartz surface rinsed from 1*M* potassium chloride, and lastly the quartz surface rinsed with 1*M* aluminum nitrate. In the temperature range previously mentioned and at a pressure interval of 25 to 60 mm. the silver surface did not induce any explosions of a mixture of 1 volume of methane to 2.4 volumes of oxygen. However, the reaction rate was considerably slower than with the hydrofluoric acid-treated quartz. Under the same conditions the potassium chloride-treated surface did not induce any explosion up to 110 mm. pressure, the reaction being greater than, but of the same order as, that in hydrofluoric acid-treated quartz. With the alumina-coated surface explosions did occur in about the same pressure and temperature ranges as the hydrofluoric acid-treated quartz. but the surface aged more rapidly, until, after 24 hours no explosion could be obtained. The conclusion was made that, in the investigation of ignition temperatures of gases and gaseous mixtures by heated surfaces, if reproducible results are desired one should use a surface which can be accurately duplicated and will not age rapidly.

The mechanism of the upper limit of ignition of a mixture of ethane and oxygen has been reported by P. Sadovnikov, *Physik Z. Sowjetunion*, 1933, **4**, 743; *Chem. Abs.*, 1934, **28**, 2979. For the derivation of an equation for the period of induction in the inflammation of gas mixtures see A. E. Malinovskii, *Acta Physicochim. (U.S.S.R.)*, 1935, **3**, 509; *Chem. Abs.*, 1936, **30**, 2387. The induction time and ignition temperature of methane-hydrogen mixtures has been discussed by H. Sachsse, *Z. Elektrochem.*, 1936, **42**, 504; *Chem. Abs.*, 1936, **30**, 6945.

DETERMINATION OF IGNITION TEMPERATURES

These determinations have long been a subject of controversy, due to the many different values obtained through the use of widely variant methods and apparatus. Dixon's work[21] on the ignition points of gaseous mixtures using a "concentric tube" apparatus, under varying conditions of pressure and time lag has been compiled by Coward.[22] Dixon's apparatus consists essentially of a glazed silica cylinder enclosed within a clay tube, the latter being wound with nichrome wire which is used for heating. Air or oxygen is admitted through the larger of two concentric tubes at the base of a silica cylinder, while the inner or smaller tube which extends to the center of the cylinder carries the gas to be studied. The burnt gases are removed at the top of the cylinder. All of the equipment is well insulated against heat losses and built to withstand high pressures.

The investigations included the mixtures: hydrogen-air (dry and also containing 5.3 per cent water vapor), hydrogen-oxygen, carbon monoxide-air (moist), carbon monoxide-hydrogen (varying concentrations of hydrogen in moist and dry air), carbon monoxide-oxygen (dry and moist). Results were also obtained for mixtures of methane, ethane, pentane, benzene, and of ethylene with either air or oxygen.

In Tables 194 and 195 are listed the rapid-ignition points, at atmospheric pressure, of some of the gases studied. These points, i.e., rapid ignition points, may be defined as the minimum temperature to which a gas and the atmosphere must be raised, prior to admixture, so that the gas inflames 0.5 second after opening the jet. The values are usually higher than the minimum temperature required to ignite such a mixture when it flows continuously from a jet. The latter are designated as ignition points of stream.

TABLE 194.—*Ignition Points of Various Gases.*

	In Oxygen		In Air	
Gas	Rapid-Ignition Point, °C.	Ignition Point of Stream, °C.	Rapid-Ignition Point, °C.	Ignition Point of Stream, °C.
Hydrogen	625	585	630	585
Carbon monoxide	687[a] 680[b]	650[c]	693[a] 683[b]	651[c]
Cyanogen	—	811	—	856

TABLE 195.—*Ignition Points of Hydrocarbons.*

	In Oxygen		In Air	
Gas	Rapid-Ignition Point, °C.	Ignition Point of Stream, °C.	Rapid-Ignition Point, °C.	Ignition Point of Stream, °C.
Methane	664	556-700	722	650-750
Ethane	628	520-630	650	520-630
Propane	—	490-570	—	—
Pentane	355	—	600	—
Ethylene	604	510	627	543
Propene	586	—	618	—
Acetylene	—	428	435	429
Benzene	685	—	710	—

The ignition temperatures tabulated show that inflammation of the various gases takes place at a lower temperature in oxygen than in air for the same pressure. In the cases of hydrogen and of carbon monoxide ignition temperatures were increased only 3° to 6°C. with the change in media from oxygen to air. With pentane the difference is 245°C. and for diethyl ether vapor, 330°C.

FIG. 224.—Types of Vessels Employed for Determination of Ignition Temperatures. (G. W. Jones, W. P. Yant, W. E. Miller and R. E. Kennedy)

A similar study has been made by Bunte and Bloch,[23] who found that for a particular gas-air mixture the lowest ignition temperature occurred not with the amount of air required for complete combustion, but rather with a mixture showing the highest reaction velocity in accordance with the mass law. Here again when oxygen was substituted for air the values of the lowest ignition temperature fell considerably.

The flash points of mixtures of methanol (anhydrous) and ethanol (99.5 per cent) with benzine have been recorded by Roberti.[24] With methanol, the flash point was said to be 9.5°C., with ethanol, 14°C.

EFFECT OF CONCENTRATION OF CERTAIN SUBSTANCES ON IGNITION TEMPERATURES

Jones[25] and co-workers investigated the ignition points of diethyl ether admixed with air or oxygen. Using the drop method apparatus (shown in Fig. 224, design D) the minimum ignition temperature was 182°C. in oxygen. With the apparatus of design B the minimum inflammation temperature in air was 304°C. Mixtures of diethyl ether vapor (containing 3.5 per cent by volume ethyl alcohol) showed higher ignition values in air in all vessels, i.e., in vessels of design B, C, D in Fig. 224, the temperatures in air were 317°, 334° and 387°C., respectively. The minimum inflammation temperatures for ethylene-air mixtures in which the concentration of ethylene varied between 3 and 38 per cent by volume, were determined in the concentric tube apparatus shown in Fig. 224, design A. Results are presented graphically in Fig. 225. Bunte and Bloch[26] noted that high hydrocarbon concentration caused higher ignition temperatures.[27]

FIG. 225.—Ignition Temperatures of Ethylene-Air Mixtures. (G. W. Jones, W. P. Yant, W. E. Miller and R. E. Kennedy)

Work by Naylor and Wheeler[28] with mixtures of ethane, propane, ethylene and air showed that formaldehyde and ethylene are formed during the lag period for ethane-air mixtures. However, the prior addition of the aldehyde to inflammable mixtures did not shorten the lag. The rate of reaction was thought to be affected more by the concentration of the hydrocarbon than by the proportion of oxygen in the mixture. Also, it was noted that the ignition temperatures decreased with increase of molecular weight of the hydrocarbon. Low rates of reaction in the case of propene were explained on the basis of steric hindrance. Dykstra and Edgar,[29] using a concentric tube apparatus similar to that employed by Dixon,[30] determined the spontaneous ignition temperatures of gasoline vapor-oxygen mixtures. For a given mixture the ignition temperatures were lowered smoothly as the oxygen to fuel ratio was increased until suddenly an abrupt drop of about 200°C. occurred with only a small change in the ratio as shown in Fig. 226. Similar abrupt changes took place in the ignition temperature also when small variations were made in the percentage of gasoline vapor in the inner tube, with the oxygen to fuel ratio constant, as shown in Fig. 227.

Effect of Fuel Vapor Concentration on Spontaneous Ignition Temperature of Gasoline. Constant Oxygen to Fuel Ratio. (F. J. Dykstra and G. Edgar)

Courtesy Industrial and Engineering Chemistry

These observers noted, using a different technique, that certain gasolines possess two distinct ignition temperatures at definite concentrations and oxygen to fuel ratio. For example, with a mixture containing 4.6 per cent gasoline vapor by volume and having an oxygen to fuel ratio of 8.2 to 1, ignition was first noted at a temperature of 280°C. as shown in Fig. 228. As the temperature was allowed to rise, inflammation occurred at short intervals until the mixture reached 314°C., at which point ignition ceased. At 444°C., inflammation commenced again, but the explosions were somewhat less violent than those in the range 280° to 314°C.

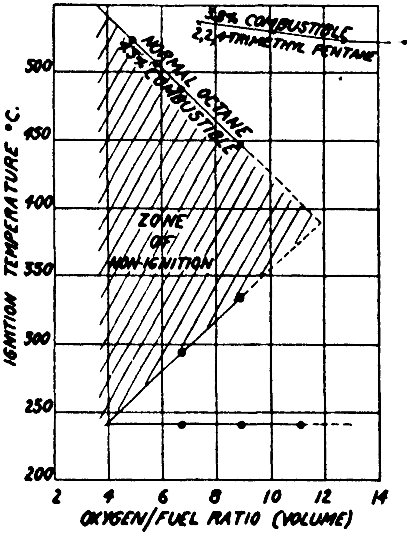

FIG. 229.
Ignition Characteristics of *n*-Octane and of Isooctane (2,2,4-Trimethylpentane). (F. J. Dykstra and G. Edgar)

Courtesy Industrial and Engineering Chemistry

These same zones of ignition and non-ignition were passed through by lowering the temperature slowly. Fig. 229 illustrates similar results obtained with two pure isomeric hydrocarbons, namely *n*-octane and 2,2,4-trimethylpentane. *n*-Octane shows zones of ignition and non-inflammability similar to those obtained for gasoline (previously discussed). A 3.8 per cent fuel vapor mixture of 2,2,4-trimethylpentane showed no ignition temperature below 523°C. and a relatively slight effect of oxygen-to-fuel ratio. The lowered temperature limit was not affected by changes in concentration of the combustible mixture, but the highest one was very sensitive to small differences. Ignition temperatures in oxygen were found to be less sensitive to variations in conditions than when determined in air.

Experiments[31] have also been carried out, using apparatus akin to that of Bunte and Bloch,[32] to study the relationship between ignition temperature and concentration of a combustible gas for the vapor-air mixtures of propane, butane, pentane, and other hydrocarbon gases. It was found that the lowest ignition temperature for a given mixture always occurred with the combustible vapor in excess and that the temperatures decreased with increasing number of carbon atoms.

EFFECT OF PRESSURE ON IGNITION TEMPERATURES

Townend and co-workers[33] studied the influence of pressure on the spontaneous ignition of mixtures comprising air and butane, pentane, hexane or isobutane. For butane-air mixtures, the ignition temperatures fell into two groups, the one, for determinations below 3 atmospheres pressure and at temperatures greater than 450°C., and the other for greater pressures and temperatures below 370°C. Also with pentane-air mixtures upon which the pressure was less than 3 atmospheres one group (of ignition temperatures) lay above 490°C., and with greater pressure there was a group lying below 350°C. A transference of ignition point from the lower to the higher range occurred at a critical (or transition) pressure dependent on the composition of the mixture. At pressures near the critical value the addition of lead tetraethyl raised the ignition point from the lower to the higher temperature. On the other hand, small additions of acetaldehyde at all pressures greater than one atmosphere produced a transference to the lower range. Further observations showed for hexane-air mixtures two regions of spontaneous ignition, one below 350°C. and the other above 495°C. Also, the pressure necessary to transfer ignition from the lower to the higher group was found to be 0.9 atmosphere for rich mixtures. In a limited pressure range just above the critical transition point, addition of 0.05 per cent lead tetraethyl raised the ignition temperatures from the lower to the higher system, as shown graphically in Fig. 230. When the mild steel lining of the explosion vessel was replaced by one of glass a lowering of the ignition points of about 20° occurred in both the higher and lower ranges. The pressure required to decrease the values, however, was always slightly greater than with the mild steel liner. In the case of isobutane-air mixtures the ignition temperatures were below 370°C. and above 390°C., pictured graphically in Fig. 231. The effect of the addition of 0.05 per cent lead tetraethyl was similar to that previously discussed and is also shown in Fig. 231.

Later investigations[34] have extended this work to include methane, ethane and propane. With the higher paraffins the ignition points lay in two well-defined temperature ranges, whereas with methane or the intermediate products to which it gives rise (on ignition) the values were confined to an upper range even at pressures up to 30 atmospheres. With ethane-air mixtures a lower temperature-ignition

tion system developed at pressures above 13 atmospheres. The presence of 1 per cent of acetaldehyde in this medium reduced the pressure limit to below 5 atmospheres. Propane-air mixtures revealed all the ignition characteristics of the higher paraffins, ignitions in the lower temperature range being greatly facilitated by the presence of small amounts of either propionaldehyde or acetaldehyde. The investigators concluded that the results further support the theory that the lower group of ignition points occur when the temperature and pressure conditions favor the survival and further oxidation of aldehydes. The higher group of ignition points were believed to result from ignition mainly of the products of thermal decomposition. Also it has been suggested that knock in an engine probably follows a compression ratio promoting ignition in the lower-temperature range. Addition of antiknock compounds raises the pressure necessary for ignition in this range.

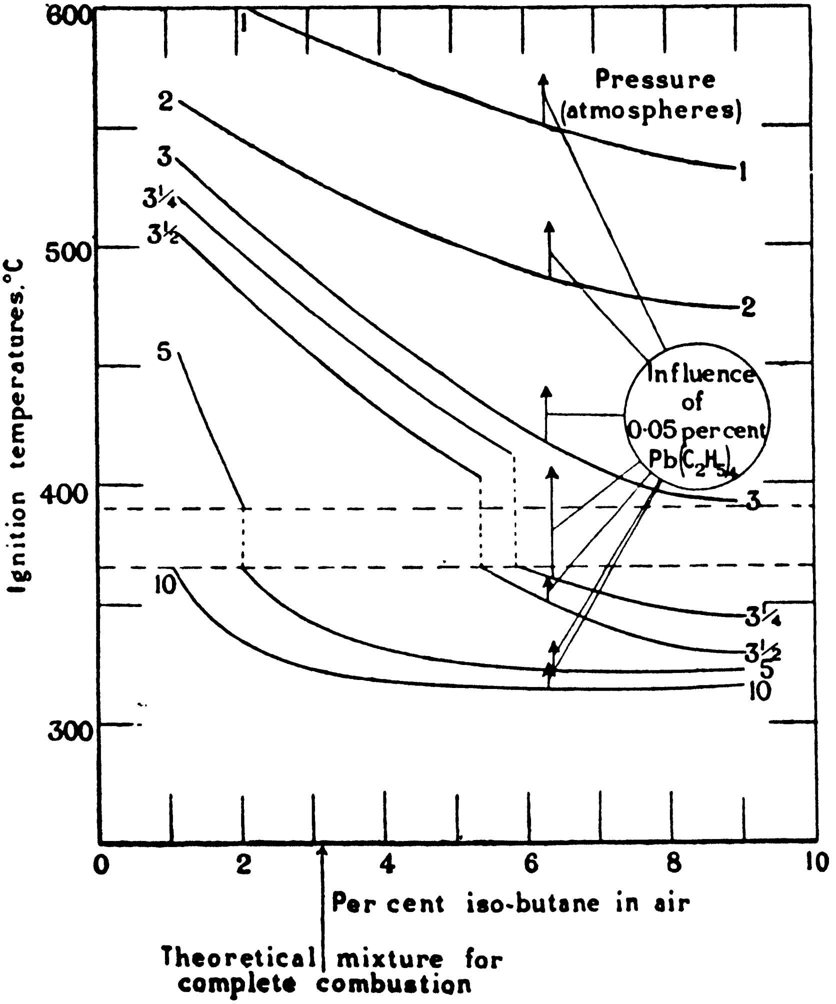

FIG. 231.—Influence of Pressure on Spontaneous Ignition of Isobutane-Air Mixtures. (D. T. A. Townend, L. L. Cohen and M. R. Mandlekar)

Neumann and Aivazov[35] advance another hypothesis which proposes that the velocity of oxidation of the hydrocarbon should increase rapidly with temperature over a wide range of pressure, and should then pass through a maximum into a region of negative temperature coefficients. They suggest that on further raising the temperature the velocity should again increase. Results obtained on the velocity of oxidation of pentane and oxygen in quartz vessels at various pressures below the ignition limit and temperature of 300-500°C. substantiated this theory and also showed two regions of thermal ignition with increasing pressure.

---

In the study of the condition of spontaneous ignition in mixtures of pentane and oxygen (1 to 8 by volume) at pressures ranging from 5 to 140 cm. Neumann and Estrovich[36] found sharp breaks in ignition temperature in the region of 60 cm. pressure. It was assumed that oxidation proceeds in two ways, that is, at higher pressures ignition is due to the oxidation of an aldehyde or an intermediate oxygenated product. On the other hand, at low pressures, conditions favor thermal decomposition of these bodies to hydrogen, carbon monoxide and methane, which require a higher temperature for ignition. These observations appeared to be closely connected with the greater probability of knocking upon increase of compression in internal combustion engines.

Naylor and Wheeler,[37] from investigations of the ignition of methane-air mixture by a heated surface, propose that the oxidation of methane is a thermal reaction catalyzed by the products of an initial slow and flameless combustion. The explanation, they believe, is not necessarily in conflict with that of chain mechanism set forth by other experimenters who worked with methane and oxygen at lower temperatures. Naylor and Wheeler found that with mixtures containing less than 10.7 per cent methane two pressure limits of ignition exist. For richer mixtures (i.e., more than 10.7 per cent methane) there was only one pressure limit. This was explained on the supposition that at low pressures the lag in ignition increases because of a change in the type of reaction, that is, from surface to gas phase, and also a change in the rate at which different mixtures become non-inflammable as a result of pre-flame combustion.

The influence of pressure on the spontaneous ignition temperatures of gasoline-air mixtures was investigated by Townend and Cohen.[38] They report that in the lower temperature zone there are two types of ignition: one, manifest by slow-travelling bluish flames ("cool flames") which result in small but fairly rapid pressure development and gaseous products rich in bodies strongly aldehydic in character; the second is true ignition manifest by brilliant white light emission accompanied by much greater pressures and explosion products practically free from intermediate oxygenated bodies. Although true ignition in the lower temperature zone is unusual at atmospheric pressure, an increase of pressure soon leads to the development of true ignition which follows the cool flame immediately. In Fig. 232, (curve 1) the data obtained on a rich (6.5 per cent by volume) gasoline-air mixture are presented graphically. Cool flames were observed within the diagonally shaded portion. At pressures below 1.15 atmospheres true ignition occurred in the higher temperature range above 472°C., but at this pressure it was also possible at 342°C.; but not between 342°C. and 472°C. Increase of pressure to 1.45 atmospheres widened the lower inflammation region to between 325° and 360°C. and at the same pressure a second inflammation was initiated at 290°C. Further rise in pressure widened both ranges so that at 1.6 atmospheres ignition occurred between 288° and 308°, between 314° and 364° and finally at all temperatures above 416°C. At pressures greater than 1.9 atmospheres inflammation was possible at all temperatures above 284°C. There are thus two pressure minima of true ignition in the lower temperature range, this type of ignition point curve being characteristic for higher paraffin hydrocarbons.

FIG. 232.—Effect of Pressure on Spontaneous Ignition Temperatures of Gasoline-Air Mixtures. (D. T. A. Townend and L. L. Cohen)

Curve 2 pertains to a mixture of like composition but employing an "ethyl" gasoline and curve 3 is the ignition point curve for a weaker (4 per cent by volume) standard gasoline-air mixture. Townend and Cohen report that knock in an engine is apparently related to a compression rate adequate to allow spontaneous ignition in the lower temperature range, which lies within the ordinary working temperatures of gasoline-air engines. The influence of an antiknock was to increase this compression rate.

Coffey and Birchall[39] observed that a gasoline-air mixture had two spontaneous ignition temperatures (at atmospheric pressure), one "ignition zone" existing from 320°C. to 335°C., then a zone of non-inflammability from 335°C. to 420°C., and finally from 420°C. upward a zone of continuous ignition. With the addition of an antiknock substance, such as aniline, in increasing amounts the lower ignition zone was narrowed until it finally disappeared. When a pro-knock or kerosene was added the lower zone was widened.

EFFECT OF WATER VAPOR ON IGNITION TEMPERATURES

Jones and Seaman[40] investigated the effect of water vapor on the ignition temperature of methane-air mixtures. These experiments were carried out using dry

The differences between the ignition temperatures for the dry and saturated gases vary somewhat with the composition, reaching a maximum of 11°C. for a mixture containing about 4 per cent of methane. The minimum value for a saturated gas occurs in mixtures with 5.5 to 6.0 per cent of methane. The dry gas has its minimum ignition temperature in mixtures containing 4.5 to 5.0 per cent methane. The results obtained for mixtures where the humidity was 20 per cent seem to coincide with those for the dry gas, but the values for the 50 per cent humid mixtures lie between those of the dry and saturated mixtures, being nearer to the dry gas values. The effect of proportions of water vapor less than 20 per cent were too slight to be decided by these tests. Studies of the influence of water vapor by Bunte and Bloch,[41] on various gas mixtures, revealed that in the case of carbon monoxide the ignition temperature was lowered, presumably because of the presence of hydrogen and hydroxyl radicals participating in the intermediate oxidation steps. Water vapor, however, raised the ignition temperature of hydrogen.

EFFECT OF VARIOUS INERT AND OTHER ADMIXTURES ON IGNITION TEMPERATURES

When argon[42] was added to methane-oxygen mixtures (containing 3 and 37 per cent methane) 3 limits of ignition were found to exist between 635° and 680°C. Although the inert gas did not affect the time lag of ignition, the lower and higher limits at 650°C. were extended, the lower limit change being in accordance with Semenov's law.[48]

[48] Semenov's law is a chain-mechanism theory developed to account for both slow reactions and explosions. The probability δ of a collision between activated reaction product and one of the reactants with sufficient energy to start branching of the stoichiometric chain increases with the temperature. If ν is the number of single reactions in the simple chain and n_0 is the specific rate of

The ratios of the concentration of argon to nitrogen and helium necessary to raise the lower limit of a methane-air mixture to one atmosphere were found by Lavrov[44] to be 1.2 and 1.73, respectively. For hydrogen-air mixtures the ratios of the concentrations of carbon dioxide, hydrogen chloride and helium to nitrogen are 1.05, 1.06 and 0.26, respectively.

Tawada[45] found that the addition of 0.1 to 0.2 per cent of ozone lowered the spontaneous ignition temperature of gasoline in an oxygen-nitrogen mixture and at the same time always shortened the lag of ignition. The addition of lubricating oils to various gasolines was found to lower the ignition temperatures. Mineral oils were found to be more effective in this respect than castor oil.[46]

IGNITION TEMPERATURE BY DROP METHOD ON PARTIALLY ENCLOSED PLATE

The apparatus used in these experiments[47] is shown in Fig. 233, the essential features being the ignition block with its cup-shaped surface for holding the material under study, the thermocouple which is inserted in a well below the cup and an aperture centered above the cup for admitting the sample. A tube built into the apparatus permits compressed air to be blown into the cup thus removing all contaminating vapors present before each run. The apparatus is also completely insulated. The investigators observed that on correlating average boiling-point and gravity (A.P.I.) with the values for the ignition temperature of petroleum fractions studied, the temperature falls with increase in the boiling point to about 600°F. in the kerosene range, after which a sudden rise to 800°F. for spontaneous ignition temperature takes place in the lubricating oil range, as shown graphically in Fig. 234. With increased gravity the ignition temperature falls sharply to a minimum and then rises slowly to a maximum. From these data the

the endothermic reaction, the velocity $= n_0\nu$. When secondary activation is considered, the velocity is $w = n_0\nu(1 - \nu\delta)$. When $\nu\delta = 1$, $w = \propto$ and the reaction is an explosion. The alterations in ν resulting from admixture of an inert gas and from collisions with the vessel walls are discussed. N. conclusion was reached that the structure of hydrocarbons may be studied from their spontaneous ignition temperatures. It was also reported that for hydrocarbons having the same number of carbon atoms the spontaneous ignition temperature decreases in the order: aromatic compounds, alkylated aromatic compounds, naphthenes, straight-chain paraffins, branched-chain paraffins and unsaturated aliphatic compounds.

COMBUSTION OF HYDROCARBONS UNDER CONSTANT VOLUME

Akita[48] reports that reaction temperatures in the oxidation of hydrocarbons vary with concentration of the hydrocarbon, the material used in the construction of the reaction tube, and other conditions. The mechanism proposed for combustion of normal paraffins is:

$$C_nH_{2n+2} \xrightarrow{O} C_nH_{2n+1}OH$$
$$C_nH_{2n+1}OH \xrightarrow{O} C_{n-1}H_{2n} + HCHO$$
$$HCHO \xrightarrow{O} H_2O + CO(\text{or } CO_2)$$

This work was extended to include the alcohols and phenols of the benzene series for which were proposed the following mechanisms.

(1)
$$C_6H_6 \xrightarrow{O} C_6H_5OH$$
$$C_6H_5OH \xrightarrow{O} CO_2 + H_2O$$

(2)
$$C_6H_5CH_3 \xrightarrow{O} C_6H_5CH_2OH$$
$$C_6H_5CH_2OH \xrightarrow{O} C_6H_6 + HCHO$$

(3)
$$C_6H_4(CH_3)_2 \xrightarrow{O} C_6H_4(CH_2OH)_2$$
$$C_6H_4(CH_2OH)_2 \xrightarrow{O} C_6H_6 + 2HCHO$$

(4)
$$C_6H_5(CH_2)_nCH_3 \xrightarrow{O} C_6H_5(CH_2)_nCH_2OH$$
$$C_6H_5(CH_2)_nCH_2OH \xrightarrow{O} C_6H_5(CH_2)_{n-1}CH_3 + HCHO$$
$$HCHO \xrightarrow{O} H_2O + CO + CO_2$$

---

This investigator also noted that the temperature at the beginning of the reaction of the hydrocarbons coincided with the spontaneous ignition temperatures.

INFLUENCE OF CATALYSTS ON IGNITION TEMPERATURES

Zerbe and co-workers[49] studied the ignition temperatures of benzene and pentane vapors in the presence of palladium and the oxides of cobalt, uranium, cadmium, manganese, nickel, magnesium, zinc, tin, lead, chromium, iron, bismuth, vanadium, aluminum and copper. For benzene vapors the ignition temperatures were considerably reduced by the presence of the above solids with the exception of aluminum oxide, lead oxide (yellow) and cuprous oxide. When pentane vapors were substituted for benzene the ignition temperatures were in general raised. In the catalytic combustion of methane-air mixtures, using an electrically heated platinum wire, it was noted by Davies[50] that as the hydrocarbon concentration was increased from 1 per cent to 5 per cent the minimum temperature of combustion was lowered from 970° to 760°C. The mechanisms of the catalytic combustion of carbon monoxide and of hydrogen were found to be different from that of methane. Although it was noted that the entire wire was not catalytically active until heated to 1300°C., in mixtures (of methane and air) where there was an excess of methane the reaction was observed to start below this figure and the temperature of the wire increased abruptly. If the wire temperature was then raised electrically it was noticed that the rate of combustion decreased and became zero at sufficiently high temperature, thus destroying the catalytic effect. When oxygen replaced air, the temperature of incipient combustion rose and the rate of combustion decreased. Davies thus proposed that the catalytic combustion of methane on platinum requires the adsorption of both methane and oxygen.

IGNITION BY COMPRESSION METHODS

The ignition of methane-air mixtures (composition 3-75 per cent methane by volume) by compression methods was investigated by Wheeler.[51] The ignitions were carried out in a pressure cylinder which was in turn connected with a low-pressure chamber by a small aperture. Ignition took place in the pressure cylinder only when the aperture connecting with the low-pressure chamber, containing a similar mixture, was not greater than 2.25 mm. in diameter. Flames shooting into the low-pressure chamber did not ignite its contents. Investigations were carried out in which each hole was covered with a thin copper diaphragm to delay the escape of gas until sufficient pressure had been built up to burst the diaphragm. Under these conditions, (with a hole 4.75 mm. and a diaphragm 0.10 mm. thick, breaking pressure of 110 atmospheres) ignition took place in the low-pressure chamber with mixtures whose concentration varied from 8 to 11 per cent in the pressure cylinder. Wheeler has also reported that the ignition of mixtures by passage of a compression wave which heats them only momentarily was not possible.

Observations have also been made by Dixon and Harwood[52] on the ignition

temperatures of varying concentrations of methane by compression methods. With 7 to 7.5 per cent methane by volume the lowest values were obtained at about 450°C. at 29 atmospheres. Mixtures from 2 to 75 per cent methane could be ignited and were found to propagate flame under higher compression and at the temperature produced by the compression. With increased pressures the ignition temperatures were observed to fall, e.g., at a pressure of one atmosphere the temperature was 735°C. but at 37 atmospheres it fell to 375°C.

IGNITION BY ELECTRICAL DISCHARGE

Experiments[53] on the inflammation of mixtures of air with methane, ethane or carbon monoxide were carried out in a closed spherical vessel in which ignition (from a secondary electrical discharge) took place at the center. This occurred more quickly when the mixture remained quiescent whereas the effect of turbulence was to require a higher ignition current. Explanation was made on the basis that general inflammation of a mixture is dependent on the production of a sufficient volume of flame around the spark-gap. If the heat so generated is dissipated by the rapid delivery of a stream of unburned and unheated mixture (which is the effect of turbulence) the flame is extinguished. Thus, to compensate for such a heat loss, it becomes necessary to use a more intense secondary discharge for ignition.

Gimmelman and Neiman[54] propose that the spark energy of methane-oxygen mixtures increases as the pressure is lowered, according to the empirical formula of Kontorova.[55] It was noted that as a function of the electrode separation, the critical energy is constant for large separations while it increases rapidly for smaller ones. Another factor believed to have influence on the critical energy is the temperature, i.e., the energy value is raised with decreasing temperature, the logarithm of the energy being proportional to the reciprocal of the temperature. These explanations and results were derived theoretically on the assumptions of a chain mechanism for the ignition process and the creation, by the spark, of active centers proportional in number to the energy of the spark.

Yumoto,[56] working with mixtures of air containing less than 5 per cent hydrogen or less than 10 per cent carbon monoxide, found that the igniting power of a short spark (i.e., one less than 4 mm.) which shows band spectra is greater than that of one exhibiting spark spectra. With long sparks (10 to 12 mm.) the igniting power was greatest on the portions of the spark where the heads of the nitrogen band appear strongly, and especially on the negative side of the spark where the heads of the first negative band are superimposed on the enhanced positive band. Yumoto reports that in a carbon monoxide-oxygen mixture (carbon monoxide 7 per cent by volume) if 0.3 per cent nitrogen was present the nitrogen bands were still bright and coincided with the maximum igniting power of the spark. Further investigations showed that the energy of the spark necessary for ignition decreased upon the addition of nitrogen up to 5 per cent (volume) after which slight increases were noted. Other observations, from plotting the amperage against the percentage of nitrogen, revealed a decided discontinuity between the interval 30-35 per cent nitrogen corresponding approximately to the composition of two volumes of oxygen to one of nitrogen. Therefore, Yumoto concluded that nitrogen is not merely a diluent, but that its action may be due to the formation of some compound.

Investigations carried out by Cohn and Spencer[57] on the effect of density and temperature on the inflammation of a hydrogenated safety fuel brought out some very interesting points. A 5-minute interval was allowed between the fuel injection into the explosion chamber and the spark so that vaporization took place completely. Otherwise for shorter intervals the explosions occurred with liquid-vapor mixtures. For the vapor-air explosions it was noted that an increase in air density lengthened the reaction time. On the other hand, for liquid-vapor-air explosions, an increase in air density from 0.00473 to 0.0095 g./cc. shortened the time of reaction. However, as the density was increased to 0.0142 g./cc., the reaction time again lengthened. The leanest mixture that would explode within a period of 5 minutes was, according to Cohn and Spencer, one corresponding to an air-fuel ratio of 20.7. For a period of 0.004 second it corresponded to one of 25. It was concluded that with an air-fuel ratio of 10 the reaction time was a minimum while the pressure was a maximum for the delayed explosions. At the higher densities and temperatures the two types of explosions acted more alike.

Coal gas-air mixtures have been studied by Sloane[58] who reports that these cannot be ignited by electric discharges between the surfaces of good insulators. Instead, he recommends using a discharge from an insulating surface to a metallic one and also a discharge between two surfaces of moderately good insulators. This type of ignition (by corona discharge) was found to work quite satisfactorily. Induction-coil discharge between glass electrodes at 100°C. produced ignition in a 15 per cent gas-air mixture. As a result of this and further experiments the conclusion was reached that the electrode temperature and the least igniting energy are lower the more concentrated the inflammable mixture. Ignition was possible between slate electrodes (4 mm. apart, with or without metal points) by means of corona discharge provided the discharge current was greater than 300 microamperes.

INCREASE OF PRESSURE DURING COMBUSTION

The question of the effect of initial temperature on the rate of pressure rise in gaseous explosions is a subject still open to investigation. Studies have been made by Pearl and Brown[59] using equipment (shown in Fig. 235 and 236) which consisted essentially of four bombs machined from solid blocks of steel. Bomb 2 of Fig. 235 had two plate-glass windows with a lens in front of each to focus the light emitted by the flame of the burning gas on a rotating drum, thus enabling measurements to be made of the time necessary for the flame to fill the bomb and also of its duration. Bombs 1 and 3 (the former not shown) differed materially in size only. Unlike bomb 2 they had no windows, were heated by gas burners, and cooled by water running over them, and their removable jackets could be filled with solid carbon dioxide. Bomb 4 was small enough to be immersed in a wide-mouthed Thermos bottle containing liquid air. Another part of the equipment was a two-cylinder four-cycle engine, one cylinder of which was operated by a pump, the other as a four-cycle gas engine being connected to a large synchronous motor operating at 1200 r.p.m. The drum shown in Fig. 235 carrying a sensitive bromide paper was held at a constant speed by a synchronous motor.

In conducting the tests, the bombs were first thoroughly purged by running nitrogen through them at above 100°C. Some of the gases studied were: acetylene, benzene, butane, carbon disulphide, ethylene, hydrogen, methane and propane. The initial weight or density of the charge was kept constant for each series of runs. Pearl and Brown observed a critical initial temperature from which the rate of pressure rise was higher than from other initial temperatures. An excess of oxygen above that theoretically needed for complete combustion, excess fuel or the presence of an inert gas (nitrogen or carbon dioxide) raised this critical initial temperature. When no diluent was present with the mixture theoretically required, the rate of rise in pressure increased uniformly as the initial temperature was lowered and no critical ignition temperature could be reached for such charges. On the other hand, in the presence of 64.7 per cent (volume) nitrogen, 13.9 per cent excess oxygen raised the critical temperature 43°C. This temperature point would have been raised 166°C. had the excess oxygen been replaced by nitrogen.

These investigators also found that when the heat capacities of the products of combustion had low temperature coefficients the explosive mixtures had high critical initial temperatures. The order of decreasing temperature coefficients was: carbon dioxide, carbon monoxide, nitrogen, oxygen, water and hydrogen; so that as the predominating products of the combustion varied from carbon dioxide to hydrogen the critical initial temperature of the explosive mixture rose. For fuels having high carbon to hydrogen ratios, this value was somewhat lower, decreasing as the ratio above increased. Another feature noted was that the critical initial temperature values at constant initial pressures were lower than at constant initial density for theoretical or nearly theoretical mixtures containing little diluent nitrogen. On the other hand, for those mixtures possessing as much or more diluent nitrogen than is in air, the critical initial temperature was higher at constant initial pressure.

FIG. 236.—Diagram of Bombs Employed in Study of Gaseous Explosions. (W. A. Pearl and G. G. Brown)

Wellard,[60] after working with fuel-air mixtures comprising ethylene, amylene and ethyl alcohol under pressures of 1, 2, and 4 atmospheres and varying rates of heating, reports with those substances having ignition temperatures above 300°C., an increase in the rate of heating causes an increase in the pressure rise due to the ignition. For example, with a speed of heating of 25° per minute and a mixture containing 38 per cent amylene, the pressure increased with temperature uniformly except when the latter was about 311°C. Wellard proposed that an initial pressure of at least 2 atmospheres and a heating rate of at least 9° per minute seem to be necessary for the spontaneous ignition of amylene-air mixtures. Further observations carried out on gasoline and hexane with ignition temperatures below 300°C. showed a decrease in pressure rise (due to ignition) with increase in the rate of heating, and above a critical rate no longer showed an ignition temperature. Measurements of the pressure rise or "shock" caused by the ignition (spontaneous or by spark), showed that it increased with temperature and was greatest at that of spontaneous ignition.

---

[60] R. Wellard, *Ann. combustibles liquides*, 1936, 11, 275; *Chem. Abs.*, 1936, 30, 5015; *Brit. Chem. Abs.* B, 1936, 1029. See *Nat. Pet. News*, 1937, 29 (16), 156.

Investigations were carried out by Mondain-Monval and Wellard[61] on the influence of temperature in the explosion of mixtures of air and hexane vapors. These mixtures were heated in a steel bomb under a pressure of 5 kilograms, and, at a given temperature, fired with a spark. The resultant pressure rise was measured by ascertaining the distance a steel point on the end of a small cylindrical piston was driven into a block of lead. The explosion forces were then plotted against the various firing temperatures. In this manner the graphical data showed that below 180°C. the explosion pressure was independent of temperature, but above this the explosion pressure increased considerably as the spontaneous ignition temperature of 232°C. was approached. This was believed to be the result of formation of alkyl peroxides. When benzene was substituted for hexane quiet combustion took place over the above temperature range, the explosion pressures being independent of firing temperature.

FLAME PROPAGATION

A theory of flame propagation, intended to supply a knowledge of the structure of the flame front during slow inflammation, has been proposed by Lewis and von Elbe.[62] The assumption is made that the highly energized atoms or radicals formed in the flame front play a more important part than heat conductivity in making the unburned gas reactive. It is thought that a small number of these energized atoms diffuse into the unburned phase and initiate chemical reaction. The sum of the thermal and chemical energy per unit of gas in all layers from the burned to the unburned phase is assumed to be constant.

The propagation of flame in fire damp explosions has been studied by Burgess[63] who reported that from observations of the explosion of methane-air mixtures in tubes having branch members at right-angles to the main tube the total distance of projection of the flame depends on the amount of release afforded to the pressure of the explosion. He assumed that by the addition of one or more side tubes ahead of the flame it is possible to increase its distance of projection. On the other hand, if a side tube joined the main tube in the region of the explosive mixture, instead of just beyond it, the distance of projection was less. The maximum total distance of projection reported by Burgess was approximately 7.25 times the original length of the explosive mixture.

Flame observations in an engine have been reported by Marvin.[64] A side-valve L-head single-cylinder engine was employed, equipped with a special head containing 30 windows and apparatus consisting of mirrors, lenses and a stroboscope fitted with a phase-changing device, enabling one to look down vertically through each window without altering the eye position. Thus it was possible alternatively to substitute a camera at the eye piece and take photographs of the various settings using the stroboscope as a high-speed shutter for the camera with each series of exposures taking 30 seconds. Progress of the flame front at any degree of crank angle was observed from the position of the windows illuminated. The photographs showed that the flame progresses in patterns roughly concentric about the point or points of ignition. "Reaction velocity" was defined as the rate at which the flame front progresses into the unburned gases. The "gas velocity" merely expresses gas motion and involves no burning. Reaction velocity has been found to vary greatly with different fuels, approaching a maximum near the equivalent mixture for any given fuel. This value may be reduced by the addition of inert gases. Marvin proposes that the flame velocities are a maximum at roughly the middle of inflammation relative to crank angle and at a minimum at the beginning and end.

STATIONARY FLAME AND ITS UTILIZATION

It has been found by Kurokawa[65] that to maintain a steady flame at the orifice of a burner the ignitible gas and air (mingled by diffusion) must flow upward at a rate just balancing that at which the flame is propagated downward. If it is assumed that combustion takes place at the conical boundary surface between the flame and a mixture containing the theoretical amount of air for complete combustion, and that neither thermal decomposition, nor partial ignition, occurs in the flame, the following relationship then exists, where v is the velocity of ignition

$$v = \frac{(1 + \alpha)Q}{\pi r\sqrt{L^2 + \gamma^2}}$$

under the theoretical air mixture, Q the quantity of gas issuing from the orifice, α the theoretical air volume of gas, L the length of the flame, and γ the radius of the orifice. When the supply pressure of gas is h, the specific gravity s, and the orifice constant K, we have the expression for Q given below.

$$Q = K\pi r^2\sqrt{h/s}$$

Therefore,

$$L = (1 + \alpha)\gamma\sqrt{h/v}\sqrt{s}$$

when γ is much less than L. This relationship Kurokawa found to hold experimentally within certain limits. Velocity of propagation of flame has also been determined by Corsinglia[66] and found inversely proportional to the square root of the specific gravity. Moreover, since the velocity v may be considered as that of the gas and air mixture produced by diffusion and gas flow from an orifice, the same relation may be derived from kinetic theory. For this reason Kurokawa reports the product $v\sqrt{s}$ is constant. The relationship was thus expressed in a straight-line equation, $H = A + BL$, in which A and B are constants. From the experimental work in which A and B were determined, it was noted that gases rich in hydrocarbons give comparatively satisfactory results, although gases containing a large proportion of inert diluent or hydrogen do not.

Investigations have also been carried out by Malinovskii and Klass[67] on the effect of temperature on the interruption of gas explosion by an electric field. These collaborators found that the minimum potential required to extinguish a nearly stationary flame between condenser plates was lower at all temperatures for a mixture consisting of 25 and 75 per cent of acetylene and air, respectively, than for a similar mixture where proportions were 20-80 per cent. Although the temperature coefficient was positive in both cases it was reported to be greater for the 20-80 per cent mixture, the flame of which was not quenched by any potential up to 1500 volts at temperatures greater than 120°C.

TEMPERATURE AND LATENT ENERGY IN FLAME GASES

The general assumption that temperatures reached as a result of the combustion of gases are equal to those calculated from the heat of combustion of the fuel and the specific heats of the products of combustion, making allowance for heat lost by radiation is reported to be in error.[68] From temperature measurements made by means of platinum thermometry during the long period of constant pressure burning (the "pre-pressure period"), it was found that the flame gases are in an abnormal condition and do not consist of merely heated carbon dioxide, steam, nitrogen or other gases. When this abnormal condition prevails, associated with it is a latent energy of large amount, and it is this factor which prevents the full development of the calculated temperatures in the inflamed gases, according to David. At atmospheric pressure the latent energy is reported to be seldom less than 15 per cent of combustion.

Another series of experiments was carried out in which the light emitted by inflamed gases contained in a closed vessel was recorded on a moving photographic film. A simultaneous pressure record was made and from this the mean temperature of the inflamed gases could be deduced. Marvin found that light was emitted not only during the explosion period, but for some time afterwards. This duration of "after-glow" increased with the density. He therefore concluded that gases, after inflammation, are in an abnormal condition and associated with this condition is latent energy, accounting for the accompanying luminosity.

MEASUREMENT OF FLAME TEMPERATURES BY THE SPECTRAL LINE-REVERSAL SYSTEM

It has been reported by Watts and Lloyd-Evans[69] that such studies have been made in the following manner. Two quartz windows were fitted into the combustion chamber of an engine. Then light from an electric arc was passed through suitable lenses and a pair of adjustable neutral wedges so as to vary its intensity. This light then emerged as a parallel beam which passed through the engine cylinder and emerged through a further lens which focused the beam onto the slit of a spectroscope. Between this latter lens and the spectroscope was inserted a stroboscope disc running at half-engine speed. In this way the light passed to the slit of the spectroscope once in each working cycle of the engine. The wedges previously mentioned were adjusted so that reversal of the sodium line (obtained by introducing a metallic salt in the fuel, e.g., a 1 per cent solution of sodium ethylate in alcohol which was added in the proportion of 15 cc. per gallon) occurred while the engine was running. The engine was then stopped and the spectroscope replaced by a monochromatic pyrometer of the disappearing filament type. Readings were obtained on the pyrometer by removing the quartz window and focusing the lens nearest the spectroscope when engine conditions became steady. In this manner it was found possible to observe temperatures over 1200°C. which could be repeated to within 15°C.

Another method for measuring engine flame temperatures has been suggested by Rassweiler and Withrow.[70] The conditions differed slightly from those previously discussed. Temperatures were measured, not at one point in the combustion chamber, but at three; near the point of ignition, near the center of the combustion space, and in the portion of the chamber where the last of the charge was burned and knocking took place if at all. These flame temperature measurements were taken under both non-knocking and knocking conditions instead of as heretofore under only non-knocking. The method of measuring the temperature was the sodium-line reversal. The L-head engine combustion chamber had two windows, placed opposite each other so that light could pass directly from an outside light source through the combustion chamber and the flames and be focused on the slit of a spectroscope. The source of light used was a General Electric projection lamp with a wide strap filament. The temperature was controlled by varying the current through the lamp. Thus from a calibration curve the temperature corresponding to current could be read. A stroboscopic shutter enabled observations in the combustion chamber to be limited to any desired portion of the engine cycle. The essential operating conditions for the engine were: jacket temperature held at 212°F., engine speed 800 r.p.m., spark advance 15°, fuel-air ratio 12 to 1, and compression ratio 4.4 to 1. The fuels used consisted of a 32 octane number gasoline for the knocking runs and a 75 octane number for the non-detonating tests. Powdered sodium carbonate was introduced in the engine to obtain a bright yellow sodium emission line as contrasted with a background of the continuous tungsten filament spectrum. As the temperature of the filament was raised it was noted that the intensity of the sodium emission decreased. When the line disappeared, the temperature of the flame and filament were the same, thus giving the flame temperature from the current-temperature curve.

It was found that under non-knocking conditions, after inflammation was complete, at about 35° past top dead center, a temperature gradient existed in the chamber from the firing end to the locality of final inflammation. For a condition where the engine was knocking, 5° before top dead center, a temperature of 4400°F. absolute at the firing end was recorded. At later angles it increased and rose to a maximum of 5000°F. absolute as the pressure increased. At 15° past top dead center, the temperature rose sharply but fell off rapidly as the pressure decreased. The temperature for the center of the chamber rose suddenly with the pressure until about 15° past top dead center. Temperature measurements could not be made at the knocking end until the knock was completed, at which point the temperature was already dropping. Under knocking conditions the temperatures at the firing end and the center did not appear to equalize, but those of the center and the knocking end approached each other quite closely for 20° after the knock. The temperatures reached a maximum several degrees earlier when the engine was knocking than when it was not. At all three positions the maxima were higher in knocking than in smooth running. During most of the expansion stroke the rate of cooling was faster after knocking than when no knocking had taken place. Heat loss to the walls was concluded to be greater, possibly because of more black-body radiation and because of the turbulence of the gases in knocking.

Flame Velocities in Mixtures of Inflammable Gases

For pentane-oxygen mixtures ignited by an electric spark, Gusev and Neiman[71] report that for a given initial pressure and temperature the mean velocity was proportional to the composition.[72] Using the mixture mentioned above under 7 atmospheres pressure and 175°C. results showed two maxima in the speed of propagation.

The effect of moist gases on flame speeds was studied by Voronkov and Sokolik[73] who used moist carbon monoxide-oxygen mixtures containing 20-92.5 per cent carbon monoxide. The experiments were carried out with pressures ranging from 200 to 400 mm. At 400 mm. there were sharp maxima for compositions corresponding to $2CO + O_2$ and $4CO + O_2$, and a sharp minimum for the gas mixture represented by $3CO + O_2$. On the other hand, at 200 mm. only the sharp maximum was noted when the ratio of gases was that indicated by $4CO + O_2$. In the explosion of equimolecular mixtures of ethylene and oxygen both undried and intensively dried with phosphorus pentoxide, the flame speeds are reported to be faster in the dried gases.[74]

FIG. 238.—Flame Pictures of a Single Engine Explosion. (G. M. Rassweiler and L. Withrow)

Further investigations of the velocity of flame motion have been made by Rassweiler and Withrow,[75] who employed a specially designed single-cylinder L-head engine possessing as its important feature the combustion chamber shown in Fig. 237, and a special motion picture camera constructed so as to be able to use continuous film. Image motion was synchronized by means of 30 lenses carried in a disk mounted on the engine crankshaft and pictures were obtained which presented an unobstructed view of the entire combustion chamber. This camera photographed 30 pictures of a single explosion at rates up to five thousand pictures per second. The pressure-time curve of this explosion was also recorded and is presented in Fig. 239. These flame pictures (Fig. 238) show the ignition spark, the spread of flame through the combustion chamber, gas movements behind the flame front, and an increase in luminosity of the burned gases near the spark plug as the explosion process proceeds and the pressure rises.

Explosive Behavior of Knocking and Non-knocking Fuels. Investigations of this nature were carried out by Thompson and Wheeler[76] who made photographic records of the flame movements and pressure development of various hydrocarbon-air mixtures. For pentane-air mixtures knock occurred only when pentane was in excess, so that it was supposed the source of the energy of the shock wave responsible for this phenomenon resides in partly burning gases behind the flame front. They noted that a measure of the anti-knock value of a fuel could be obtained either from the lowest initial pressure with which a mixture containing nearly the theoretical quantity of fuel for complete combustion can produce a knocking explosion, or, alternatively, with a constant initial pressure, from the concentration of a fuel required to produce an explosion the flame of which is striated. Thompson and Wheeler further compared the explosive characteristics of pentane, *n*-hexane, benzene, cyclohexane, *n*-heptane, and ethyl alcohol with those of commercial fuels.

These investigators also report that the character of a knocking explosion is completely changed if nitrogen of the air is replaced by either argon or helium, all other conditions remaining the same. For example, a 3.7 per cent pentane-air mixture of an initial pressure of 3 atmospheres and 70°C., gave a strong knock on exploding. On the other hand, detonation of a 3.7 per cent pentane-oxygen-argon mixture under the same conditions of temperature and pressure gave a quiet explosion despite the fact that flame speed in the former mixture was twice that in the latter. Continuous illumination occurred behind the flame front in the pentane-oxygen-argon mixture with regular pressure development. Thus it was concluded that during the later stages of flame propagation in a knockless pentane-oxygen-argon explosion there must be less residual energy than in the knocking pentane-oxygen-nitrogen explosion. It was supposed that nitrogen plays an active part in a knocking explosion, perhaps as an absorber of energy or a producer of oxides.

MECHANISM OF COMBUSTION

Many investigations have been undertaken on the combustion mechanism as it takes place in the internal combustion engine, principally to determine the cause of knock or detonation. By photographic means, Withrow and Boyd[77] made simultaneous flame and pressure studies of individual explosions in a gasoline engine. The essential feature in the apparatus employed was a special cylinder head fitted with a quartz window so that a camera could be mounted above the window to record pictures of the flames inside the cylinder. Flame and pressure records were synchronized by electrical means. From the records so obtained the following conclusions were made: starting at the point of a spark, a flame, or a narrow combustion zone, moves progressively through the charge. Oxidation is apparently complete within this narrow zone but the products of combustion to the rear of the flame front continue to emit light for a time. In a non-knocking explosion the flame moves at a relatively constant velocity to the end of the combustion space. However, in a knocking explosion the rate of inflammation of the latter portion of the charge is very much higher than normal, so high in fact, that at the instant of knock the flame appears simultaneously throughout the unburned portion of the charge.[78] This phenomenon is accompanied by a very rapid rise in cylinder pressure, the magnitude of which is related to the intensity of the knock.

Subsequent spectroscopic studies[79] revealed that most of the light visible in the afterglow, i.e., points through which the flame front had already passed, came from the same molecular carriers as the light given off during the reaction between carbon monoxide and oxygen. This indicated that the hydrocarbons are burned in the flame front, furnishing confirmatory evidence for the conclusion that in a knocking explosion the sudden pressure rise is due to rapid burning of the last portion of the fuel charge with little or no contribution from the gases through which the flame has already passed. The visible light from the flame front under non-knocking conditions, and also under knocking conditions prior to knock, was

[77] L. Withrow and T. A. Boyd, *Ind. Eng. Chem.*, 1931, **23**, 539; *Chem. Abs.*, 1931, **25**, 3475; *Brit. Chem. Abs.* B, 1931, 618. A previous method of investigation, using a quick-acting water-cooled sampling valve attached to the cylinder for removing gases at any desired time for inspection, proved to be inadequate for differentiating some of the characteristics of knocking and non-knocking explosions. found to come largely from CH and C_2 radicals, but when knock began, absorption bands from those radicals appeared only feebly in the flame front. Since OH radicals were also detected in the explosion mixtures[80] one suggested explanation for the decreased intensity of CH and C_2 bands was that reactions may have been taking place with these OH radicals in a knocking explosion.

$$\begin{aligned} C_2 + OH &\longrightarrow CO + CH \\ CH + OH &\longrightarrow CO + H_2 \end{aligned}$$

It was advanced that the presence of OH radicals may be the result of the thermal dissociation of water.

Further work[81] indicated that chemical changes occur in the air-fuel mixtures ahead of the flame fronts and that these changes are different in knocking than in non-knocking explosions. The conclusion was made that the observed weakening of the CH and C_2 bands in the knocking zone is the result of the disappearance of a large portion of the original hydrocarbons before arrival of the flames, with the formation of compounds which do not give CH and C_2 radicals when they inflame. Reactions in the knocking zone just prior to inflammation were assumed to be, in part at least, oxidation processes.[82] A reason for the assumption was the detection of formaldehyde as a reaction product in this zone under knocking conditions and its absence from zones ahead of the flame front in non-knocking explosions.[83] Since formaldehyde did not produce knock when introduced into the engine with the intake air, it appeared that the compound is not alone responsible for knock. However, the general relationship between the appearance of this aldehyde and the subsequent occurrence of knock indicated that the compound is associated with a reaction sequence which leads to spontaneous ignition in the non-inflamed gases ahead of the flame front, which ignition was assumed to be the cause of knock.

By varying engine conditions so that the knock intensity was increased from zero upwards, formaldehyde appeared under conditions just below the threshold of knock and increased in concentration to a slight extent after passing conditions of incipient knock, but the concentration soon reached a maximum which was barely altered by more severe knocking. With variables adjusted slightly below the threshold, preflame reactions appeared to take place also, but their progress was so slow that spontaneous inflammation did not occur before the flames reached the end of the combustion chamber.

It was shown that the addition of tetraethyl lead eliminated knocking by retarding the burning of the last part of the fuel charge to a rate which is normal for non-knocking explosions. At the same time the concentration of formaldehyde in the knocking zone was not reduced. However, the use of tetraethyl lead in the fuel to remove knock did restore the intensities of the CH and C_2 bands as detected spectroscopically in the burning gases in the knocking zone. Both atomic lead and lead monoxide were found in the flame fronts and there was strong evidence to assume that the lead monoxide was being reduced in the non-inflamed portion of the fuel charge. Thus, it appeared that this monoxide was acting as an oxidizing agent at the same time that the metallic lead was effecting anti-knock action.[84]

Several workers have assumed that detonation in an engine is a direct result of peroxide formation during combustion. For example, Dumanois[85] noted that, in the direct oxidation of saturated hydrocarbons by air, alkyl peroxides are formed between 200° and 300°C. Also, in operating an engine at 270°C. on a hexane-air mixture under detonating conditions, peroxides and aldehydes were found in the exhaust gases after the ignition had been cut off and the engine kept running with an auxiliary motor. Slight explosions heard after switching off the engine were assumed to be the result of exothermic spontaneous decomposition of peroxides formed during compression. Since it was observed that peroxides begin to form at about 120-130°C. and are decomposed below 300°C., the proposal was made that detonation could be eliminated by operating the engine with a sufficiently high fuel-mixing temperature and great enough speed to pass over the peroxide-forming stage.[86]

In experiments conducted by Serruys,[87] detonation occurred in a one-cylinder engine when the air was preheated to 250°C. With a temperature of 310°C. a severe knock resulted. In view of the fact that peroxides decompose below 300°C., it was concluded that they were not the sole cause of detonation but when present favored its occurrence. The suggestion was made that during combustion the temperature and pressure of the unburned gases increase irregularly so that at some point the inflammation limit is reached prematurely, causing a sudden increase in heat evolution and pressure, which, if sufficiently large, will start an explosive wave which results in knocking.[88] Dumanois[89] assumed that, in knocking explosions occurring above temperatures at which peroxides do not form, the detonation is the result of spontaneous ignition of the charge.[90]

In a critical review of various theories of detonation, Darche[91] gave the following opinions: Detonation results neither from simultaneous combustion of the unburned gases in the latter portion of the charge nor from the propagation of an explosive wave. Although peroxides can produce an accelerating effect at the beginning of combustion they probably no longer exist when detonation takes place and are therefore not the determining cause of this phenomenon. The action of antiknock compounds in small amounts is to retard combustion rather than to act on peroxides. Detonation in engines is characterized by a very rapid, but not explosive, combustion of fresh gases with a concurrent acceleration of combustion of the carbon monoxide existing just behind the flame front so that the phenomenon of knocking is not localized but involves a general acceleration of combustion. Darche considered that an important factor in eliminating detonation is to alter the design of the motor so that an automatic regulation of combustion can be effected to vary with operating conditions.

[90] Carbonaceous deposits in engine cylinders may have a beneficial influence on detonation as a result of the high temperatures maintained on their surfaces because of poor thermal conductivity. See G. Roberti, *Gazz. chim. ital.*, 1933, **63**, 872; *Chem. Abs.*, 1934, **28**, 5646; *Brit. Chem. Abs.* **B**, 1934, 309.

Studies of the combustion process in an engine by means of a sampling valve employed to remove gases at any stage in the engine cycle[92] showed that in the combustion occurring in the knocking zone prior to the passage of the flame, aldehydes and substances behaving as peroxides were formed. The quantity of the latter increased with greater knock intensity and decreased when tetraethyl lead was added to the fuel. Incorporation of aldehydes with the fuel did not affect the knock tendency nor the amount of peroxides formed. The latter were subsequently found to be largely nitrogen peroxide with small percentages of organic peroxides. The main source responsible for the formation of nitrogen peroxide was believed to be the hot active surface of the exhaust valve of the engine rather than the flame itself. Knocking was attributed to the disruptive explosion of intermediate oxidation products by branched-chain reactions.[93]

Ubbelohde,[94] in formulating a mechanism for the combustion of paraffin hydrocarbons, assumed that the chain carriers must be of a nature similar to those involved in the combustion of aldehydes and ethers. Engine knocking was thought to be related to reactions of paraffins of more than 3 or 4 carbon atoms during combustion in the low-temperature region (250-320°C.). The chain reaction for aldehydes involves two carriers which are considered of great importance in the combustion of hydrocarbons.

$$\mathrm{RC({=}O)}\text{—} + \mathrm{O_2} \longrightarrow \mathrm{RC({=}O)OO}\text{—}$$
$$\mathrm{RC({=}O)OO}\text{—} + \mathrm{RC({=}O)H} \longrightarrow \mathrm{RC({=}O)OOH} + \mathrm{RC({=}O)}\text{—}$$

In the combustion of paraffins, each hydrocarbon molecule first undergoes partial dehydrogenation, as for example by the action of the aldehyde peroxide radical.

$$\mathrm{RC({=}O)OO}\text{—} + \mathrm{RCH_3} \longrightarrow \mathrm{RC({=}O)OOH} + \mathrm{RCH_2}$$
$$\mathrm{RCH_2} + \mathrm{O_2} \longrightarrow \mathrm{RCH_2O_2}$$
$$\mathrm{RCH_2O_2} + \mathrm{RCH_3} \longrightarrow \mathrm{RCH_2OOH} + \mathrm{RCH_2}$$

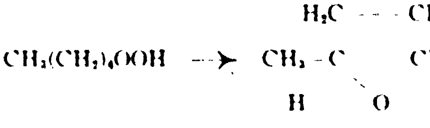
Other possibilities in this chain reaction are that the alkyl hydroperoxide can rearrange to an aldehyde and water.

$$\mathrm{RCH_2OOH} \longrightarrow \mathrm{RCHO} + \mathrm{H_2O}$$

or decomposition may take place,

$$\mathrm{RCH_2OOH} \longrightarrow \mathrm{RCH_2O}\text{—} + \text{—}\mathrm{OH}$$

Also, when the higher paraffins are involved, formation of oxygen ring compounds may occur:



In the oxidation of *n*-heptane with air[95] the initial stage of reaction was found to begin at 252°C. and to reach a maximum at 370°C. This initial stage was found to consist chiefly in the formation and decomposition of peroxides, including hydrogen peroxide and compounds of the type $HOCH_2O_2R$. At 110-115°C. the peroxides yielded ketones, aldehydes, alcohols, acids and carbon monoxide and dioxide. Gasolines containing appreciable percentages of aromatic hydrocarbons are said to have a smaller tendency to form peroxides than have pure hydrocarbons during combustion. Also, it is reported that the addition of from 0.2 to 2 per cent of aromatic hydroxy or amino compounds will inhibit or prevent peroxide formation in a gasoline during oxidation.[96] Ethanol, methanol and benzene have been found to exert a similar effect.[97]

Boerlage and Van Dyck[98] consider that detonation is the result of excessive compression during combustion. In an air-fuel mixture burning without detonation the flame progresses smoothly, but in a knocking combustion the last portion of the mixture, or "end gas," is compressed as a result of the advancing flame until a simultaneous explosive ignition occurs. This same type of reaction would occur if the original mixture were sufficiently compressed. Suggestions made for avoiding detonation were to cool the "end gas" or to increase the speed of travel of the compressing flame (e.g., by turbulence) so that the quantity of "end gas" exploding is negligible, owing to the fact that the chemical reactions leading to spontaneous ignition require time. It was believed that an important factor in hydrocarbon combustion is decomposition before reaction with oxygen.

Rice[99] also considered that there is probably a preliminary decomposition of hydrocarbons into smaller units, chiefly olefins and paraffins, partly from the thermal effect and partly from attack of molecular fragments on the original hydrocarbons. Since in thermal disruption one molecule is suddenly replaced by several smaller molecules, an extensive decomposition would have a two-fold result: (1) The pressure increase would be equivalent to raising the engine compression 5 to 25 per cent. (2) The rate of oxidation of the fuel would be greatly increased because of the larger number of fuel molecules per unit volume. Thus, the knocking tendency would be expected to be greater with an increasing number of moles of decomposition products per mole of original hydrocarbon. In this case an efficient antiknock compound would be one which would decrease the number of moles of decomposition product.

ANTIKNOCK OR KNOCK-SUPPRESSING COMPOUNDS

Although many of the substances which fall under this classification have received previous mention,[100] they are further discussed here because of their steadily increasing importance. The influence of the chemical nature of the fuel on the antidetonating power of the latter (expressed as octane number) was determined by Roberti[101] for a large number of the following: saturated hydrocarbons, olefins, aromatic hydrocarbons, naphthenes and others. These investigations disclosed that the resistance to detonation in the open-chain hydrocarbons decreased with increase in the number of carbon atoms, but increased in the presence of side chains and with compactness of the molecule. Double bonds were also found to aid the anti-detonating power, their influence being greater, the nearer the double bond was to the center of the molecule. Although cyclization increased the octane number, the addition of small quantities of such compounds as lead tetraethyl or iron carbonyl increased considerably the ability of the hydrocarbons as anti-detonants.

The effect of the addition of 10 to 20 per cent of benzene, toluene, or either methyl, ethyl, propyl, butyl, isobutyl or isoamyl alcohol to gasoline was studied by Aubert and Duchene.[102] They reported that detonation was retarded by these substances up to 145°C. From 148° to 154°C. benzene and toluene seemed to have little effect, although the alcohols remained still active. Of the pure hydrocarbons with which Aubert and Duchene worked, hexane gave auto-ignition, 3-methylpentane and isohexane detonated to some extent, and 2,3-dimethylbutane was found to be inert. Further studies revealed that cyclohexene and cyclohexadiene showed auto-ignition whereas 1-hexene and cyclohexane were resistant to detonation. The injection of ethyl or methyl alcohol with fuel acts as a regulator and completely suppresses knocking, according to Aubert, Clerget and Duchene[103] who proposed this for the combustion of heavy oils. They also suggested that benzyl alcohol, benzoic and oenanthylic aldehyde may be substituted for the alcohols previously mentioned.

The use of isopentane[104] and isopropyl ether[105] in amounts constituting 30 per cent by weight of the non-knocking fuel has been described. Another fuel[106] is that obtained by cracking methane and its gaseous homologues. In one instance the product thus secured contained 8 volumes of propane plus butene, 32 volumes of ethylene, 11.6 volumes of hydrogen, 11 volumes of ethane plus propane and 1.2 volumes of nitrogen.

Some of the more interesting aromatic compounds suggested are: those of the benzene series which have been converted to nitrogen bases by heating under pressure and at elevated temperatures in the presence of ammonia gas,[107] alkylated compounds formed by treating gasoline with olefins in the presence of preformed acid sludge derived from the treatment of hydrocarbon material with sulphuric acid,[108] esters of a dibasic acid such as butyl oxalate or butyl phthalate or other mono or diakyl oxalate or phthalate,[109] benzene or acetone solutions of nitro compounds of aniline,[110] e.g., tetranitromethylaniline or hexanitrodiphenylamine and terpenes (e.g., pinene, terpineol, or camphor). Tetralin peroxide[111] has been used also, especially in Diesel fuels. Pyzel[112] suggests a motor fuel for compression ignition engines to which has been added a mineral oil insoluble in liquid sulphur dioxide and of which an appreciable portion boils below 400°C.

Many organo-metallic compounds have been investigated as anti-detonants. Some of those which have been reported are: lithium[113] or thallium alkyls or aryls, e.g., primary butyl lithium, organic ditellurides[114] such as diphenylene ditelluride, selenium compounds, for example, phenyl diselenocyanate[115] and also organic derivatives of metallocyanic acids, exemplified by the tetraisopropyl ester of hydroferrocyanic acid.[116] The use of the copper, nickel, and cobalt[117] compounds of salicylalallylamine, salicylalmethylamine, β-naphtholallylamine, protocatechualethylamine and the condensation products of allylamine and acetylacetone have also been considered as antiknock agents. Employment of various lead alkyls has been proposed by Voorhees.[118]

Other substances which have been recommended are polymerized nickel carbonyl,[119] and iron carbonyl.[120] To this latter compound are usually added compounds containing oxygen or nitrogen, as for example, toluidine or quinone,[121] soluble organic compounds of the benzene series, isobutyl alcohol, aldehydes or ketones[122] and monomethylaniline or dimethylaniline.[123] Danner[124] suggests incorporation of a small proportion of a metallic nitrosocarbonyl, e.g., cobalt nitrosocarbonyl, to the hydrocarbon fuel oil to reduce knocking. A mixture of the chlorides of uranium and vanadium dissolved in acetone has also been proposed.[125]

Another organo-metallic compound whose importance is widely recognized is tetraethyl lead. The effectiveness of this substance in increasing the critical compression ratio of individual hydrocarbons has been studied by Campbell, Signaigo,

Lovell and Boyd.[126] Paraffins, olefins, naphthenes, aromatics and unsaturated cyclic hydrocarbons were investigated and critical compression ratios were plotted against increases in compression for an addition of 1 cc. of tetraethyl lead per gallon. This is shown graphically in Fig. 240. In this instance the minus sign indicates that addition of the lead compound caused an increase in knock intensity or decrease in compression ratio for border-line or incipient knock. In using Fig. 240, one must remember that the lines passing through the points of different classifications do not necessarily represent functions nor do they have any absolute significance. There is also indicated an area representative of an approximate location of commercial gasolines. Since this area is relatively small, values of 0.1 to 0.3 ratio per cc. might be contrasted with values ten times as great for certain aromatic, paraffin, and naphthene hydrocarbons. The line drawn roughly through the paraffin and naphthene hydrocarbons may indicate that lead is progressively more effective in those materials of higher antiknock value. However, in the case of such compounds as alpha-olefins, diolefins and acetylene homologues, the line through their classification is noted to be nearly vertical. In other words, the effectiveness of lead

shows little variation irrespective of the critical compression ratios of the hydrocarbons under consideration. A line showing the location of certain unsaturated cyclic compounds such as cyclopentadiene derivatives and as well, certain aromatics with unsaturated side chains, indicates a progressive lowering of the effectiveness of lead in them with increase in the critical compression ratios of the compounds. In a few rare instances lead has a "negative" effect, that is, tetraethyl lead acts as a knock inducer and the critical compression ratio is lowered by the addition of the lead compound.

Results of further investigations of the relationship of structure and lead effectiveness are also shown graphically in Fig. 241 giving data obtained on the aliphatic double- and triple-bonded compounds. For convenience, the effectiveness of lead (as measured by the increase in the critical compression ratio) has been plotted against the number of carbon atoms in the molecule. The compounds in which lead is more effective appear to be those which have a double bond removed from the end of the molecule. In Fig. 242 the effectiveness of lead in the compound has been plotted against the position of the unsaturated linkage for the pentenes and some heptenes and heptynes. Although the data were incomplete they do indicate that as the double bond moved toward the center of the molecule the effectiveness of lead in the compound increased. side chains, shows that for the saturated side chain the lead is most effective although with unsaturation of the side chain there is a decrease in the lead respondency. Those compounds which contained a triple bond in what might be called a "conjugated" position to the benzene ring exhibited a negative lead effect, and the hydrocarbon 1-phenyl-1,3-butadiene appeared unaffected by lead. In Fig. 244 these latter relationships are presented, thus showing the effect of the successive introduction of double bonds into some cyclic compounds. In the series cyclohexane, cyclohexene and cyclohexadiene, the effect of the lead becomes progressively less and eventually negative. Similar relationships were observed in the series cyclopentane, cyclopentene and cyclopentadiene. Other investigations were also carried out with ethylbenzene and phenylethylene. Tetraethyl lead affected the critical compression ratios of a few hydrocarbons greatest at low concentrations as shown in Fig. 245.

The thermal decomposition of tetraethyl lead in benzene solution, both in the absence and presence of ethylene and hydrogen, has been studied by Cramer.[127] He found that although two hours were required to complete the reaction at 240-275°C., the presence of methane gas was not detected; the paraffin fraction consisted of ethane with small amounts of butane. The liquid reaction products (in addition to benzene) were light colored oils and were believed to be derived from the tetraethyl lead and added ethylene. Cramer noted with few exceptions close agreement between the determined and calculated values for the liquid reaction products. He further concluded that these reactions are largely independent of wide variation in pressures, as well as relatively small temperature differences. It was also observed that practically the same amounts of unreacted ethylene were obtained from widely varying proportions of tetraethyl lead and ethylene. Attempts to decom-

pose any quantity of tetraethyl lead in the absence of a solvent gave very inconsistent results.

MEASUREMENT OF KNOCK RATING

Although a detailed discussion of the test engines, reference fuels and procedures used for the determination of knock rating, or anti-detonating value, for various fuels and fuel mixtures is beyond the scope of this book, nevertheless because of the vast amount of work which has been done on the standardization of procedures and equipment, some mention of these is not out of place. The question[128] of standardization of test methods and equipment received little consideration until 1928 when (in the United States) the Co-operative Fuel Research Committee undertook the development of a uniform test method. This work has been carried out in conjunction with interested groups in England, Germany, France and Holland.[129] Horning[130] points out that the popularity of the Co-operative Fuel

Research (C.F.R.) engine may be attributed to its universality, ruggedness and relatively low cost.

Reference Standards Used in the Measurement of Motor Knock. The relative tendencies to knock in an engine have been measured by Lovell and co-workers[131] for naphthene hydrocarbon-gasoline mixtures. The results were expressed in terms of the aniline equivalent[132] which was defined as the number of centigram-moles of aniline that must be added to a reference fuel to make 1000 cc. of a fuel equivalent in knocking tendency to a molal solution of the hydrocarbon in the reference gasoline, provided the hydrocarbon knocked less than the reference fuel. When the hydrocarbon knocked more than the reference fuel the aniline equivalent was the number of centigram-moles of aniline added to a 1-molal solution of the hydrocarbon in the reference gasoline to make a fuel that was equivalent in knocking tendency to the reference gasoline. Further investigations[133] were made on hydrocarbons of the aromatic series alone and in admixture with gasoline. The measurements of the tendency of these substances to knock was carried out in a single-cylinder, variable-compression engine equipped with an evaporative cooling system and fitted with a bouncing-pin indicator. The results expressed in aniline equivalents, some of which are listed in Table 197, are for mixtures of the hydrocarbon with gasoline.

TABLE 197.—*Effect of Structure on Resistance to Knocking*

Hydrocarbon	Aniline Equivalent	Hydrocarbon	Aniline Equivalent
Cyclopentadiene	34	Phenylethylene	20
Dicyclopentadiene	65	Ethylbenzene	19
Dimethylfulvene	61	3-Phenylpropyne	8
Methylphenylfulvene	36	1,2-Methylethylbenzene	15
1,3-Cyclohexadiene	39	Pseudocumene	20
1,4-Cyclohexadiene	29	Tetrahydronaphthalene	19

Other experiments[134] were made using a wider variety of pure hydrocarbons. Comparisons were then made on the basis of the compression ratio for border-line or incipient knock in a single-cylinder variable-compression engine. This compression or "critical compression ratio," is defined as that at which knock becomes just audible in a quiet room when the engine is running at full load, engine speed 600 r.p.m., jacket water boiling, no external heat applied to mixture, mixture ratio for maximum power and spark timing for maximum power. The results so obtained, some of which are reported in Table 198, will of course vary in some instances with changes in the conditions under which the engine is run.

The data appeared to indicate that for the aliphatics there is an increasing tendency to knock with increasing length of the carbon chain as illustrated by Fig. 247, methane showing the least tendency. Saturated cyclic hydrocarbons exhibit even greater tendency to knocking than do the corresponding aromatic hydrocarbons, though less than for paraffins. Cyclohexane derivatives for the most part are comparable with many commercial gasolines in detonation qualities. Although two and three double bonds within the ring exert a strong antiknock effect, a solitary double bond produces comparatively little effect. Cyclopentene was noted to knock

Trimethylphenylallene	36	8.3

more than cyclopentane although this was an exceptional case. An increase in the length of the side chain was observed to increase the tendency for knock in both the aromatics and naphthenes although branching of the side chain produced the opposite effect.

FIG. 247.—Critical Compression Ratios of Paraffin Hydrocarbons. (W. G. Lovell, J. M. Campbell and T. A. Boyd)

Another method of measuring knock rating is that of comparing the engine performance of the fuel with that of various mixtures of isooctane (2,2,4-trimethylpentane) and *n*-heptane. The octane number of a fuel is defined as the percentage of isooctane (the antiknock agent) in an isooctane-heptane blend which gives a knock tendency equal to that of the fuel tested.[135]

For the purpose of expressing the knock ratings of pure hydrocarbons in terms of octane numbers, Garner[136] and associates employed the term "blending octane number" as an index of the behavior of a hydrocarbon in altering the octane number of a reference fuel. Calculations were based on the assumption that a straight-line mixture relationship holds for blends of hydrocarbons and a reference fuel in concentrations up to about 25 per cent. Thus, a blend containing 15 per cent added pure hydrocarbon would be given a rating of 15 per cent of the octane number of the hydrocarbon plus 85 per cent of the value of the reference fuel. Although "blending octane numbers" are not exactly the same as actual octane numbers they give an indication of the effectiveness of a hydrocarbon as an antiknock. For paraffins and naphthenes the two types of ratings were found to be approximately the same, but the blending octane numbers of aromatics were lower and those of olefins were higher than the actual octane numbers.

FIG. 248.—Comparison of Critical Compression Ratios of Unsaturates with the Corresponding Paraffin Hydrocarbons. (W. G. Lovell, J. M. Campbell and T. A. Boyd)

Neptune and Trimble,[137] investigating lower-boiling hydrocarbons, found that the octane numbers of the 4-carbon olefins are lower than their blending octane numbers. When blended with gasoline in equal proportion there is a greater difference between iso- and *n*-pentane than between iso- and *n*-butane. However, with incorporation of *n*- or isobutane to give finished products of the same vapor pressure, the same antiknock effectiveness was noted. Substitution of *n*- and isopentane for the corresponding butanes indicated that isopentane was the most effective antidetonant. Neptune and Trimble believe small proportions of 4-carbon hydrocarbons present in motor fuels have been responsible in some instances for improved antiknock properties. For 1-heptene[138] the knock rating was determined in a 20 per cent (vol.) blend and the blending octane number found to be 79.5. When the value of this compound was compared with that of representative 7-carbon atom hydrocarbons of other series, it was noted that the introduction of a double bond into the heptane molecule in the α-position increased the blending octane number. A triple bond in the same position further increased the blending octane number but not to so great an extent.

[138] A. R. Bowen, A. W. Nash and F. H. Garner, *Nature*, 1933, **132**, 410; *Chem. Abs.*, 1933, **27**, 5955.

Becker and Kass[139] report that although the most direct method of determining octane numbers is by comparison of samples with blends of isooctane and normal heptane, the cost of the latter prohibits their use in routine testing. As a substitute for these hydrocarbons, they suggest standard reference fuels having octane numbers of 44 and 76 as determined with a C.F.R. engine. The latter fuels are made from straight-run naphthas which are applicable for use in multicylinder engines.

A procedure for rating aviation fuels is that designated as the "Allowable Boost Ratio" method.[140] This is defined as the ratio of the boost pressure[140a] for the sample at incipient knock to the boost pressure for the standard (pure isooctane) at incipient knock. The reported advantages of this method are: the test conditions more closely approximate those of the supercharged aero engine, the scale has no upper limit, and the incipient knock is closer to practice than the heavy knock needed in the C.F.R. test.

In view of certain defects of the octane scale for rating motor fuels, Evans, Dodds and Garner[141] worked out a pressure scale based on the compression just under that at which knocking took place. This scale does not involve the peculiarities of behavior of fuels consequent upon their varying temperature susceptibilities, but at the same time it is easily correlated with the octane-heptane scale on any particular engine. The difficulties encountered in determining octane numbers from 85 to 100 by the C.F.R. motor method are avoided. Also the engine used in the latter operation is unsatisfactory for octane numbers above 85. The procedure, then, is to note incipient knock by ear or preferably by microphone or temperature plug; and to determine the pressure. From the latter value the octane number can be read off the calibration pressure-octane number curve previously established for the particular engine. Other methods that have been suggested are: an electromagnetic device for determining pressure variations which may be used to study knock in motors[142] and comparison of the utilizable powers of two gasolines. In the latter case, fuels are valued by their "synthetic indexes" which may be defined as the ratio of the maximum power produced by the gasoline to that produced by a standard fuel in a standard motor under definite conditions of temperature and compression, both fuels being fed at the knock limit and giving the same percentage of carbon monoxide in the exhaust.[143]

Relation Between Constitution and Antiknock Value of Hydrocarbons

It has been shown by Hofmann, Berlin and Schmidt[144] that cyclohexene and butadiene lose in antiknock properties upon being dimerized to dicyclohexene and dibutadiene. The octane ratings for cyclohexene and butadiene were 70-71 and 83-84, respectively, but after dimerization became 53-54 and 60-61, respectively. Further experiments carried out by Schmidt[145] also substantiate the work of Lovell, Campbell and Boyd (*q.v.*). Several of the paraffins, unsaturated hydrocarbons, naphthenes and aromatics were studied as well as the following alcohols: ethyl, *n*-propyl, *n*-butyl, isopropyl, isobutyl and isoamyl, and cyclohexanol and methylcyclohexanol. The results showed that paraffins as a class give the lowest and aromatics the highest octane numbers, while methyl groups in a branched chain and hydroxyl and amino radicals all raise the octane number. The 5-membered ring naphthenes gave higher octane numbers than the corresponding 6-membered compounds. It was also noted that the octane numbers of unsaturates decreased during storage except in the case of the aromatics with unsaturated side chains. With the monohydric alcohols the octane number became less with increasing molecular weight.

PROCEDURE USED FOR KNOCK-RATING DETERMINATIONS

A complete detailed description of these procedures will not be found here as this is beyond the scope of the book as previously mentioned, but an enumeration of methods will be made. The bouncing-pin method for the determination of knock rating has been widely used.[146a] Another procedure, described by Dumanois,[147] depends upon ascertaining the extra heat imparted to the cooling water when detonation occurs. The inlet and outlet cooling-water temperatures are measured for reference-fuel blends knocking respectively more and less than the fuel under test. The rating of the fuel under investigation is obtained by interpolation. Dumanois found that an increase of 10 per cent benzol in the reference fuel caused a decrease of 0.25°C. between inlet and outlet water temperatures.

MacCoull and Stanton[148] propose an electrical acoustic method for the measurement of engine knock. Oscillograms were taken of the knock disturbance, and measurements were made of the energy in various frequency bands. The C.F.R. standard engine developed a pronounced peak in knock energy at frequencies between about 6,000 and 7,000 cycles per second, while the L-head design of this same engine had a peak between 3,000 and 4,000 cycles per second.

MacCoull[149] reports that but little difference could be detected between the bouncing-pin and a throttle-audibility method,[150] when used in fuel matching, and therefore concluded no appreciable advantage exists for one method over the other in regard to accuracy. Some of the results are shown in Table 200.

TABLE 200. *Benzol Equivalents by Bouncing-Pin and Throttle-Audibility Methods on the Series-30 Ethyl Gasoline Corporation Engine.*

Tetraethyl Lead Content cc. per Gal.	Benzol Equivalent, Per Cent	
	Bouncing-Pin	Throttle-Audibility
1	13	16
2	30	31

4	44	46

FACTORS AFFECTING KNOCK-RATING DETERMINATION

It has been pointed out by Hubner and Murphy[151] that some automobile engines rate fuels higher in octane value than the Research (C.F.R.) Method while others rate the same fuels lower. After an examination of various types of engine design, it was shown that the inclined valve-in-head design with a central sparking plug gave the highest performance and best agreement with laboratory tests under cool running conditions such as those of the C.F.R. method.[152]

[152] For a discussion of correlation of Research Method ratings, A.S.T.M. rating and actual road tests see C. B. Veal, *S.A.E. Journal*, 1935, **36**, 165.

Schmidt and Seeber [153] studying the effect of various factors on detonation in a single cylinder engine with variable compression found that the octane number increased with richness of the gasoline-air mixture, but decreased with advanced ignition (over a range of 5° to 20°) as the air-intake and jacket temperatures rose.

The effect of temperature on knock-rating was studied by Peletier[154] who noted that increase of cooling liquid temperature in the test engines used resulted in an increase in knock intensity at otherwise equal conditions. In studying the knock-rating of various aviation fuels, Pye[155] observed that cylinder and gas temperatures are the most important variables in the operating conditions. Bonnier and Moynot[156] working with a C.F.R. motor showed that when knock was audible the temperature of the exhaust gases increased with the antiknock value of the fuel, the rate of increase being related directly to compression ratio. When there was no knock this temperature was approximately constant, but decreased with increased compression. Other investigations[157] by these workers further confirm their conclusions. Under non-detonating conditions, the exhaust temperature remained practically constant at a given compression ratio and mixture strength. The temperature they found normally fell with weakening of the mixture.

Brown and Marshall[158] report that for maximum fuel efficiency an engine should be run at a temperature just below the dew point of the fuel. Endo and Furuya[159] observed that when the inlet mixture temperature was high (150°C.), an "ethylized" fuel was better than one blended with benzol or ethyl alcohol. The antiknock property of standard fuels decreased as the temperature rose; the higher the octane number of the fuel the greater was the effect of temperature. Jacket and cylinder-head temperatures[160] were found to affect the relative knock-rating, while humidity and air temperature[161] affected the octane numbers of secondary detonation standards. Other factors which have been studied are: influence of carburetor setting and spark timing,[162] and the effect of sound intensity[163]

Relationships between the knocking power of light fuels and their physical properties have been investigated to some extent. For example, a correlation has been found between the octane number and the specific parachor of certain fuels.[164]

In the equation: $p = 1/d \times \sigma^{1/4}$, p = specific parachor, d = density and σ = surface tension. The parachor of a hydrocarbon is dependent upon its chemical constitution and is decreased by the presence of side chains, double bonds and ring structures. For hydrocarbons of the same boiling point a decrease in parachor was noted in the sequence: paraffin, unsaturated compounds, naphthenes and aromatics. The octane numbers of hydrocarbons were found to be inversely proportional to the parachor over the boiling point range 90-150°C. From a study of various benzines, these investigators also report that approximate determinations of the octane numbers can be made from relationships with physical constants other than the parachor. Marder[165] points out that the anti-detonating qualities are inversely related to the density (d_{20}) of the fuels.[165a] Fuels with high densities were more affected by changes in test conditions (in a given motor) than those of low density. Marder proposes that the parachor and density (d_{20}) may be used to correlate differences in octane numbers arising from different conditions of test.

THE EFFECT OF TETRAETHYL LEAD ON KNOCK RATINGS

Hebl, Rendel and Garton[166] brought out the fact that, in addition to its antiknock value, every gasoline has a property which may be defined as its "lead susceptibility" and which determines the amount of increase in antiknock value for any given concentration of tetraethyl lead. A special chart was devised, called an "Ethyl Blending Chart," into which were embodied the factors which determine the octane number of an ethylized gasoline in their proper relation. It was found that by use of this chart,[167] shown in Fig. 249, the reliability of estimated octane numbers of ethylized gasolines could be considerably improved, and also the lead susceptibility of the base gasoline could be conveniently determined. The five factors which determine the octane number of any ethylized gasoline are:

1. The effectiveness of isooctane at different concentrations in raising the antiknock value of isooctane-heptane mixtures, i.e., the relative "dimensions" of octane numbers in different parts of the scale.
2. The effectiveness of tetraethyl lead at different concentrations. This compound is more effective in small concentrations and, as more is added to a gasoline, its effect gradually diminishes.
3. The octane number of the base gasoline before tetraethyl lead is added.
4. The "lead susceptibility" of the gasoline.
5. The number of cubic centimeters of tetraethyl lead added per gallon of gasoline, called the "lead requirement" of the fuel.

In using the chart shown in Fig. 249 the lead susceptibility of any of the gasolines plotted can be determined by extending a line from the star on the left-hand side of the chart through to the lead susceptibility scale on the right-hand side so that the line is parallel to the line already plotted for the gasoline in question. It was believed that the lead susceptibility of a gasoline is not dependent on the hydrocarbons alone but may be markedly affected by impurities e.g., disulphides and other sulphur compounds. The reduction of lead susceptibility has been studied by Schulze and Buell,[168] who report that the disulphides, except carbon disulphide, have the most harmful, the thioethers less and thiocyclic compounds the least harmful, effect on lead response. Comparisons between some aliphatic sulphides and between some aliphatic disulphides show that the reduction of octane number is greater with homologues of higher molecular weight and with branched chain isomers. Considerable lowering of octane number was also noted when aromatic disulphides were present and the concentraton of tetraethyl lead low.

Investigations by Tongberg[169] and co-workers on the susceptibility of several gasolines (or fractions of these) to tetraethyl lead and aniline revealed that octane number and lead suspectibility are not dependent alone on the boiling range of the fuel. Fractions of the same boiling range (prepared from various gasolines) had

(Data obtained with C.F.R. engine using A.S.T.M. method D357-36T)

1. Stabilized natural gasoline
2. Cracked gasoline
3. Cracked gasoline (50 per cent) + West Texas straight-run gasoline (50 per cent)
4. West Texas straight-run gasoline
5. Mid-Continent straight-run gasoline

considerably different octane numbers and lead susceptibilities. This was attributed to different types of hydrocarbons and sulphur compounds being present which boil in the same ranges. It is the opinion of Tongberg and co-workers that the effect of hydrocarbon structure in these fractions should not be overlooked. The addition of aniline up to 7 (volume) per cent gave a practically linear increase in octane number for straight-run gasolines, whereas tetraethyl lead gave only small increases in octane number when over 2 to 3 cc. per gallon were used. In cracked gasoline, aniline gave a greater increase in octane number for the first 2 per cent than it did for the second 2 per cent, but from 2 to 7 per cent the increase in octane number was again linear. This property of aniline suggested the possibility that it might supplement the action of tetraethyl lead by acting independently. Certain cracked gasolines were easily brought up to 80 octane number or higher by the use of aniline and tetraethyl lead together, whereas the use of tetraethyl lead alone failed to accomplish this result.

[169] C. O. Tongberg, D. Quiggle, E. M. Foy and M. R. Fenske, *Ind. Eng. Chem.*, 1936, **28**, 792; *J. Inst. Pet. Tech.*, 1936, **22**, 355A; *Chem. Abs.*, 1936, **30**, 6177. See also W. T. Ziegenhain, *Oil, Gas J.*, 1934, **33** (32), 51 for a discussion of a curve that may be used to determine the amount of lead that must be added to give a desired octane number to a gasoline.

Reports from other investigators[170] revealed that the reason for all the effects being smaller for cracked than for straight-run gasoline is inherent in the hydrocarbon constituents of the gasoline and not due to sulphur compounds or other impurities. Brown and Singer[171] found that cracked gasolines were superior to leaded gasolines of the same octane number.

Effect of Type of Gasoline on Knock Rating

Tongberg and co-workers[172] suggest that the three possible ways of obtaining a motor fuel of higher antiknock value from Pennsylvania gasoline are as follows: the fractions of high antiknock value could be segregated, the fractions of high antiknock value and high blending value could be blended with fractions of only moderate antiknock value to give greater volume of fuel, and the fractions of best octane number could be blended with those most responsive to tetraethyl lead.

Trimble[173] in comparing the antiknock characteristics of vapor-recovery and natural gasoline blends, found that the octane ratings for the former were higher than those of equivalent natural gasoline blends regardless of the method of test. However, natural gasoline was found to be appreciably more lead responsive than vapor recovery gasoline. It was also observed[174] that the antiknock properties of certain gasolines could be increased by cracking the latter at a temperature of 450°C. and at a pressure from 40 to 110 atmospheres.

The separation of knock inducing constituents from motor fuels has been carried out by Voorhees.[175] This method involves distilling the motor fuel into narrow boiling fractions which are refrigerated to give liquid and solid constituents, the latter being rejected.

Detonation in the Diesel Type Engine

Investigations on the ignition quality of Diesel fuels showed that it was advantageous to base all ignition data on reference fuels, for which on theoretical considerations, cetene, $C_{16}H_{32}$, and mesitylene, C_9H_{12}, were suggested, since the former substance will ignite readily in a Diesel engine while the latter does not.[176] The routine rating of fuels is made by measuring the difference in delay of ignition at two pressures, 15 and 30 atmospheres, and expressing the result in terms of reference fuels so as to give each fuel a "cetene number," this being the percentage of cetene in the standard fuel blend which matches the sample tested.[176a] Ignition in this type of engine is said to depend principally upon the chemical structure of the fuel, and the air temperature and pressure, whereas combustion is dependent on correct mixture strength and turbulence. Knock is caused by delay during ignition and is the effect of a too rapid change in pressure rise. In a weakly constructed engine a too-rapid pressure rise will cause what is known as rough running.[177]

BLENDED MOTOR FUELS

From time to time various blends of gasoline with other materials, e.g., ethanol, methanol, benzene, or ketones, as well as the use of other liquid or even gaseous fuels have been proposed to replace gasoline in the spark-ignited internal combustion engine. Also a few such blends have been suggested for the Diesel type of engine. Reasons for this development are various, the principal ones being of an economic nature, as for example, fear of a gasoline shortage, the substantially higher cost of this fuel in non-petroleum producing countries, and the utilization of fuel sources within individual nations to make them less dependent on outside sources. A more important but apparently less contributing factor in developing fuel blends has been the desire to improve fuels from various standpoints.[178]

Alcohol Blends. Much attention has been devoted to the employment of alcohols, particularly ethanol, in gasoline blends. In many of the European countries laws have been passed requiring the use of alcohol-gasoline blends as motor fuels mainly as a proposal to benefit agricultural interests.[179] Mixtures containing up to 25 or 30 per cent alcohol have been advocated in order to consume the surplus.[180] Also, in the United States some effort has been made to utilize fuels of this type.[181] The assumptions on which this proposal was made are summarized by Egloff and Morrell[182] as follows: (a) alcohol-gasoline is a superior motor fuel, (b) it is more economical than gasoline, (c) there is an impending shortage of crude oil[183] which would be conserved by use of alcohol, (d) European experience upholds the practicability of the plan, and (e) use of such blends will solve the economic problems of agriculture to some extent. Many investigators, including Egloff and Morrell, point out that some of these assumptions are erroneous.

[176a] "Cetane number" has also been used to determine the ignition quality of Diesel fuels. This is defined (A. L. Foster, *Nat. Pet. News*, 1936, **28** (4), 19) as the numerical value of the percentage of cetane in a blend with methylnaphthalene which shows the same ignition quality as that of a given fuel tested. See also P. H. Schweitzer and T. B Hetzel, *Oil Gas J.*, 1936, **34** (36), 36; *J. Inst. Pet. Tech.*, 1936, **22**, 161A; *Chem. Abs.*, 1936, **30**, 2739. F. H. Garner, *J. Inst. One of the primary objections to blends of ethanol or methanol with gasoline is that the alcohol tends to separate in the presence of small percentages of water, although, when anhydrous, ethanol is miscible with gasoline over a wide temperature range.[184] However, the water tolerance of ethanol-gasoline mixtures may be increased by the addition of a liquid or solid blending agent. Among these proposed are benzene and toluene,[185] hexahydronaphthalene,[186] acetone, ethyl ether, *n*-butyl alcohol, isoamyl alcohol[187] and isopropyl alcohol.[188] Blenders suggested by Bereslavsky[189] include menthol, geraniol, citronellol, steam-distilled pine oil, terpineol, fenchyl alcohol and borneol, used in the proportions: 5 per cent blender, 85 per cent gasoline, and 10 per cent anhydrous alcohol.

In the case of methanol, there is more difficulty in blending with gasoline unless aromatic hydrocarbons are present. Howes,[190] and Gordon,[191] report extensive studies on the solubility behavior of methanol and the use of blending agents. The solubility of this alcohol in paraffins is rather low whereas in aromatics it is quite high. Hence one of the blending agents suggested is benzol. However, it is stated that the higher aliphatic alcohols are more efficient in this respect.[192] According to Shepherd[193] the addition of 10 to 15 per cent acetone greatly increases the miscibility of methanol and gasoline.

Some of the advantages and disadvantages of ethanol-gasoline blends as motor fuels are pointed out by Egloff and Morrell.[194] Ethanol has a high octane rating and increases the antiknock properties of gasoline to which it is added.[195] Thus, 10 per cent of ethanol raised the octane rating of a 63 octane gasoline to 72 and of a 61 octane rating to 70. At the same time there is an over-all increase in fuel consumption of 5 per cent for every 10 per cent of alcohol added. Even with improvements in engine design to obtain the highest useful compression ratio it was pointed out that because of the lower calorific value of alcohol[196] there would still be an over-all increase in fuel consumption of 2 per cent with a 10 per cent blend, and of 3.8 per cent with 20 per cent of alcohol.[197]

Since ethanol has a higher ignition temperature and a higher latent heat of vaporization than gasoline, Egloff and Morrell state that cold starting will be more difficult.[198] Warm starting would also be interfered with because of the greater volatility of the blends at higher temperatures.[199] This is indicated in the distillation curves for mixtures of gasoline with various percentages of ethanol. See Fig. 250. Another difficulty pointed out for these blends is the effect on vapor lock tendencies. Vapor lock occurs in a fuel system when too much vapor fuel is present in proportion to liquid fuel so that the engine receives an insufficient supply of the latter.[200] It was found that for the temperature range 105° to 135°F. addition of 5 per cent ethanol doubled the ratio of vapor volume to liquid volume as compared with that for gasoline alone. In Table 201 the relationship of alcohol percentage to the temperature at which vapor lock occurs is presented. From this it is seen that 1-10 per cent blends of alcohol result in appreciable lowering of vapor-lock temperature. However, Bridgeman[201] states that this tendency can be overcome if the gasoline used for blending has a lower vapor pressure than that of the gasoline with which the blend is to be compared. Also, it is asserted that

[198] On the other hand it has been stated that the flash point of a gasoline is raised from −38°C. to −30°C. on addition of 20 per cent ethanol and that starting in cold weather can be aided by preheating the air supplied to the engine. See G. Roberti, *Energica termica*, 1934, **2**, 211; *Chimie et industrie*, 1934, **33**, 352; *Chem. Abs.*, 1935, **29**, 1133.

[199] See, however, O. Wawrzinoik, *Automobiltech. Z.*, 1933, **36**, 464, 496, *Chem. Abs.*, 1934, **28**, 1501, who states that the type of fuel has but little influence on the starting characteristics of an engine.

[200] For data on the total and partial vapor pressures of mixtures of ethanol with various gasoline hydrocarbons see, Y. Nagai and N. Ishii, *Proc. Imp. Acad. (Tokyo)*, 1935, **11**, 23, *J. Soc. Chem. Ind. Japan*, 1935, **38**, Suppl. binding, 86; *Chem. Abs.*, 1935, **29**, 3491, 3805. Also N. Ishii, *J. Soc. Chem. Ind. Japan*, 1935, **38**, Suppl. binding, 659, 705, *Chem. Abs.*, 1936, **30**, 2725, 3199; *Brit. Chem. Abs.* **B**, 1936, 356.

[201] O. C. Bridgeman, *Ind. Eng. Chem.*, 1936, **28**, 1102; *Chem. Abs.*, 1936, **30**, 8572, *J. Inst. Pet. Tech.*, 1936, **22**, 507A; *Brit. Chem. Abs.* **B**, 1936, 1076.

freedom from vapor lock can be obtained by proper design of fuel lines to handle alcohol blends.

Other disadvantages reported are that there is likely to be corrosion of containers and fuel systems unless the blends are kept absolutely water-free,[202] and that under conditions where the alcohol undergoes only partial combustion, organic acids are formed which will cause corrosion of cylinders and exhaust manifolds, especially if condensation of moisture occurs in the presence of combustion products. Such conditions would be promoted by low temperatures and intermittent operation of the engine.[203] Also it was pointed out that ethanol-gasoline blends cause overheating (of motors) which, however, has one advantage in that carbon formation decreases. On the other hand, lubrication is likely to be impaired because of an increased tendency to burn the lubricating oil film from the cylinder walls. One suggested method for overcoming this is to add lubricating oil to the fuel. Another is to incorporate 0.5 per cent of oleic acid in the lubricating oil.[204]

In summarizing the reports of various investigations of alcohol-gasoline blends, Christensen[205] concludes that properly prepared fuels of this type containing up to 25 per cent alcohol may be used interchangeably with gasoline of equal antiknock rating. Also he considered that the slight difference in fuel consumption was not of great importance and stated that the various reports of abnormal corrosion by alcohol fuels have been traced to use of corrosive denaturants. Winter operation was said to be particularly pleasing because of the elimination (by alcohol) of ice-formation in the fuel system.[206]

Bridgeman,[207] in analyzing the differences between alcohol blends and gasoline itself, stated that for a fair comparison of performance a common basis must be established since the properties of fuels vary with the conditions of testing. If no adjustment is made in carburetor or spark settings when comparing the two types of fuel some cars will show more fuel consumption and some less with a 10 per cent alcohol blend than with gasoline alone for the same power output. This is attributed to the fact that the blends require a smaller air-to-fuel ratio than gasoline for maximum power[208] and that on the average, carburetor settings are distributed equally on each side of the 12:1 ratio for gasoline. With 20 and 40 per cent blends, however, the tendency would be for higher fuel consumption. On the other hand, if the spark and carburetor settings are varied to suit the individual fuel, there will be an increase of 3 to 4 per cent in fuel consumption with a 10 per cent blend and about double this amount with a 20 per cent blend. Also, if advantage is taken of the higher compression ratio, a properly designed engine will give better power and acceleration with an alcohol blend than with gasoline alone. However, it was also stated that no matter what gain in performance can be obtained by better engine design with alcohol blends, still better performance per gallon will be secured with gasoline of higher octane number in the same engine.[209]

Benzene Blends. In some instances alcohol blends contain considerable percentages of benzene or commercial benzol. Proponents of this type of fuel state that it is superior in many respects to a simple alcohol-gasoline blend or to a benzol-gasoline blend.[210] Representative proportions are gasoline 50-65 per cent, benzene 20-40 per cent and alcohol 10-20 per cent.[211] It has been pointed out that because of the high melting point of benzene (5.5°C.) the proportions of components in this type of blend are limited somewhat by the temperatures at which the fuel is to be used.[212] The water tolerance of such fuels is said to increase with the percentage of alcohol[213] but as in the case of the alcohol-gasoline mixtures blending agents are found to be helpful. For example, the presence of 0.9 per cent of pyridine oleate is said to permit the tolerance of 0.5 part of water in a mixture of 18 parts methanol, 18 parts benzene and 54 parts of gasoline.[214] An investigation of various homogenizers for a blend of 40 per cent alcohol, 40 per cent gasoline and 20 per cent benzene has been made by Grossman.[215] α-Naphthol was found to be most effective with β-naphthol and ethyl ether somewhat less so. Other substances tried were benzene, naphthalene and a middle oil from gas coal tar. The effect of the agents is shown in Table 202.

TABLE 202.—*Homogenizing Agents for Mixed Fuels.*

	Fuel Alone	5% Naphthalene	5% Benzol	10% Benzol	5% Middle Oil	10% Middle Oil	5% Ether	10% Ether	5% β-Naphthol	5% α-Naphthol
Temp. of Separation °C.	−6	−11	−11	−16	−14	−23	−23	−44	−22	−28
Percentage of Water Added to Cause Separation at 18°C.	0.9	1.1	1.0	1.2	1.3	1.7	1.6	2.2	2.1	2.2

Comp. of Fuel: 95% Alcohol—40%; Gasoline—40%; Benzene—20%

Other Blends. Mixtures of benzene, or more usually of crude benzol, containing benzene and some of its homologues, with gasoline are employed to some extent as motor fuels.[216] Other organic liquids suggested for admixture with gasoline to improve its characteristics from various standpoints include ethyl ether, acetone[217] and ethyl peroxide.[218] It is reported that isopropyl ether is as good as isooctane for blending with gasoline to improve octane rating.[219] A 74-octane gasoline was raised to 100 octane value by blending with 40 per cent isopropyl ether and 3 cc. of lead tetraethyl per gallon.

---

[209] Polymer gasoline is one source of such fuel. See G. Egloff, *Ind. Eng. Chem.*, 1936, **28**, 1461; *Chem. Abs.*, 1937, **31**, 1189. See also Chapter 26

Livraghi[220] produced a fuel, said to have high antiknock value, by mixing 40 to 60 per cent by weight of methanol or ethanol with 60 to 40 per cent of light oils or crude benzol from coal or oil shale, adding 2 per cent of naphthalene and subjecting the mixture to thermal cracking at 350-500°C. Other fuels containing alcohol include alcohol, ether and kerosene,[221] alcohol, benzene and 10 per cent water,[222] alcohol (94 per cent), water (5 per cent), gasoline (0.5 per cent) and aniline (0.5 per cent),[223] and alcohol (6) nitrobenzene (3) amyl acetate (1) and a petroleum fraction (10 parts).[224] A mixture of 90 per cent alcohol and 10 per cent acetone saturated with acetylene has also been recommended.[225] A fuel said to contain triethylmethane and trimethylmethane may be made by passing a mixture of vapors of acetyl chloride and ethanol at 200-250°C. over an iron-nickel catalyst.[226]

Annaratone[227] proposed as a motor fuel 59 per cent of ethanol and heptane, 15 per cent of toluene, amyl alcohol and *p*-xylene and 25 per cent of methylcyclohexanol, decahydronaphthalene and tetrahydronaphthalene.

Among various solid materials which have been suggested for improving motor fuels (by incorporation of small percentages in the fuel) are included biphenyl, naphthalene[228] camphor[229] menthol, *p*-dichlorobenzene[230] alkylarylketones and polynitro compounds, e.g., 2,4,6,trinitro-1-methyl-3-*ter*-butylbenzene.[231] Also, it has been proposed to add to motor fuel refined liquid decomposition products obtained from the distillation of rubber.[232] According to Greenstreet,[233] kerosene and Diesel fuels are made more completely combustible by incorporating an oxidizing agent, e.g., a nitrate or peroxide, together with a stabilizing agent such as an amido compound.

Of interest in the consideration of motor fuels are the various proposals to utilize gaseous materials either carried as such in compressed or dissolved form[234] or generated in an apparatus attached to the vehicle.[235] Thus, a mixture 20 to 30 per cent ethane and ethylene, 30 to 40 per cent propene and butene and 30 per cent propane, butane and pentane separated from coke-oven or cracking gases is suggested.[236] Hydrogen, used either alone[237] or in conjunction with liquid hydrocarbon fuels, has also been proposed.[238] Acetylene dissolved in furfural and acetone is advocated by Classen.[239]

A proposal has been made to utilize such materials as hydrorubber, isobutene polymers, polystyrene and aldol polymers of isobutyraldehyde and diacetone alcohol as sources of motor fuel.[240] The materials are depolymerized with the aid of phosphoric acid or soda lime (as needed) and the products fed to the engine.

Chapter 45

Miscellaneous Oxidation Reactions. Alcohols, Denaturants and Other Products

In a number of the preceding chapters the oxidation of individual hydrocarbons or of certain petroleum fractions has been considered. The products of such reactions are principally ketones, alcohols, esters, aldehydes and various types of aliphatic and aromatic acids and anhydrides. The effect of autoxidation on certain distillates, particularly gasoline and transformer or lubricating oils, has been pointed out. In this chapter are included the production of other compounds, such as alcohols, by oxidation, and the utilization of these petroleum fractions in the preparation of many differing kinds of materials, e.g., denaturants, insecticides, solvents, synthetic resins and waxes, and emulsifying agents. The aliphatic carboxylic acids such as formic acid have been suggested for use in preparation of pickling inhibitors. The organic acid is reacted with sulphurized cinchona bark alkaloid, such as sulphurized quinoidine, and used with dilute sulphuric acid in cleaning metals.[1] Oxidation processes such as that of dehydrogenation are considered. It has been proposed, for instance, that a catalyst capable of dehydrogenating cyclohexane to benzene[2] be made by soaking active carbon in ammonium molybdate, lead nitrate and phosphoric acid and heating (at 300°C.) in a current of sulphur or selenium hydride. The addition reactions involving carbon monoxide constitute another type of oxidation. One instance of this type is the reaction for preparing aliphatic acids by reacting vaporized alcohols and carbon monoxide over a catalyst such as chromic acid on silica gel.[3]

Mild or limited oxidation is sometimes employed in refining processes, particularly when readily polymerized or resinified constituents are to be removed. In some instances sulphur compounds present as impurities may be preferentially oxidized to sulphur dioxide, sulphur and oxides of carbon and thus be removed. A brief review of such methods is included.

OXYGEN AS A POLYMERIZATION CATALYST

The conditions for polymerizing olefins in the absence of a catalyst indicate that a definite pressure-temperature relationship exists, according to Wiezevich and Whiteley.[4] Thus, a pressure of about 2050 pounds per square inch is needed to initiate the polymerization of ethylene in a steel bomb at 345°C. If the temperature is lowered to 335°C., a pressure of 2760 pounds per square inch is required. These conditions they report, are about the minimum for polymerization in the absence of a catalyst, whereas, in order to obtain better rates of reaction, higher pressures or temperatures are needed. The investigators state that for optimum conditions, the polymerization of ethylene without a catalyst should be conducted at 430°C. under 2760 pounds per square inch pressure. Higher pressures or temperatures are required in the polymerization of heavier olefins under like conditions.

However, the polymerization of such olefins proceeds at much lower temperatures and pressures if a small amount of oxygen is added. The amount of oxygen used may vary within quite wide limits, but the amount employed is generally less than that required to react with the olefins, or to dehydrogenate the unsaturates. The addition of oxygen, they find, is needed only to start the polymerization reaction, which, once started, proceeds rapidly and smoothly at the same relatively mild conditions of temperature and pressure without addition of further oxygen. The optimum conditions of temperature and pressure at which the oxygen should be added depend to some extent on the type of apparatus, the method of treatment, and the olefins used. The exact conditions are best determined by experiment. However, they find that it is generally most satisfactory to add the oxygen to the olefins preheated to a temperature of 200° to 400°C., though other temperatures may be used. The initial pressure to be used (between 10 and 200 atmospheres) depends on the temperature employed. During the reaction, due to polymerization, the pressure may decrease even to atmospheric. According to Wiezevich and Whiteley, with higher molecular weight olefins pressures higher than those needed in the polymerization of ethylene are needed to obtain equivalent yields of liquid products. For example, under the conditions of temperature suitable for polymerization of ethylene at 60 atmospheres pressure, 80 atmospheres are needed for propene and 95 atmospheres for butene. The amount of oxygen added also depends on the operating conditions, large additions tending toward the production of carbon, although the effect of the oxygen disappears entirely at very low concentrations. Ratios of 0.01 to 0.4 mole of oxygen per mole of olefin are the outside limits, beyond which the operation is unsatisfactory. Ratios between 0.03 and 0.2 are most satisfactory. The mole ratio of oxygen required goes in inverse ratio to the molecular weight of the olefin treated. Thus, for ethylene greater mole ratios of oxygen are required than are needed for propene, butene and heavier unsaturates.

The reaction may be conducted in the presence of contact materials such as broken fire brick, silica, alumina or metal wool, which may or may not possess catalytic power *per se* in this type of reaction. The degree of polymerization may be controlled (at given operating conditions) by increase or decrease in contact time. The decrease of pressure observed during the polymerization in batch operation may be used as a rough index of the extent to which the process has proceeded. Long contact (8 to 10 hours) is desirable for more complete reaction, yields of 95 per cent (based on the reacting olefins) being obtained in this way. Shorter contact tends toward the production of lighter liquid products in smaller yields.[5]

Faber[6] has reported that natural gas can be treated with air sufficient only for partial combustion to produce gasoline and fuel gas. The mixture is maintained at a temperature of 500° to 980°C. in a reaction zone by the heat of combustion of the small part oxidized. It is said that no carbon black is formed, but that heavier gasoline hydrocarbons can then be extracted from the residual gas. Oxidation polymerization has been proposed as a method of removing polymerizable material from fuel oils. It has been suggested that this may be accomplished by subjecting the oil vapors to a refluxing action in a dephlegmator tower, while an oxidizing gas such as air is directly added to the tower to accelerate the separation of the polymerized materials.[7]

---

[5] For a more complete discussion of polymerization processes, see Chapter 26.

[6] W. F. Faber, U. S. P. 1,961,288, June 5, 1934, to V. N. Roadstrum; *Brit. Chem. Abs.* B, 1935, 295; *J. Inst. Pet. Tech.*, 1934, 20, 500A; *Chem. Abs.*, 1934, 28, 4898.

Oxidation polymerization of asphaltic base oil residues, either those resulting from cracking or non-cracking processes, may be made to yield commercial asphalts. Rose[8] proposes a blend of oily distillate cylinder oil stock, a non-cracking distillation residue free of lubricating oil, and a residue from cracking operations as raw material in this type of oxidation. The blended material is subjected to a mild oxidation, and the asphalt separated from the resulting material. Bray and Beckwith[8a] have produced an asphalt by an oxidation of similar asphaltic residue oils, and report that the separation into oil and bitumen constituents may be made satisfactorily by the use of selective solvents, such as liquid propane. The oil constituent so extracted may be treated with liquid sulphur dioxide to bring about separation into a raffinate and an extract. This second extract is mixed with the bitumen produced in the first step, and further oxidized with air. An asphalt is produced which is characterized by a relatively lower penetration power for the same melting point, and a relatively higher susceptibility to temperature change than the asphalt produced by the primary oxidation. Ragatz[9] reports that the most satisfactory temperature for air oxidation of asphaltic residuum oils to asphalt appears to be about 175°C. The oxidized material is heated to a temperature of about 350°C. to bring about polymerization of the oil fractions present in the asphalt, while sufficient pressure (about 25 pounds per square inch) is maintained to prevent major volatilization of the vaporizable oil fractions.

Légé[10] reports a method of producing either naphthenes, or, carrying the process of dehydrogenation to its limit, coke, by reacting solid, liquid or gaseous hydrocarbons with oxygen in the presence of strong sulphuric acid. Ferric, nickelic or cupric compounds soluble in the sulphuric acid present are added as catalysts. The oils are then blown with steam, or steam and air, under atmospheric pressure. If a temperature of 200° to 250°C. is employed, naphthenes result; if the temperature is raised to 250-300°C., coke is produced.

REFINING BY OXIDATION PROCESSES

According to Herzenberg,[10a] active oxygen attacks sulphur compounds present in petroleum more readily than it does olefinic and unsaturated materials. By this means, he finds, sulphur compounds may be almost entirely eliminated from the petroleum treated. His research was conducted with Mexican Panuco oil containing a total of 5 per cent sulphur as thiophenes, mercaptans, hydrothiophenes and six-membered ring compounds, such as pentamethylene sulphide. The thiophenes were most resistant to oxidation, ring scission in this case requiring a large excess of active oxygen. Benedict[11] reports desulphurizing hydrocarbons in the vapor phase by the use of oxygen (air) and ammonia over a catalyst of activated carbon. Temperatures higher than 120°C. are necessary. An oxidation promoter such as pyridine or hydroquinone may be added to the hydrocarbon oil treated, according to Chebotar.[12] As little as 0.05 to 0.3 per cent is sufficient, and the distillate is then treated with air in the presence of an oil-soluble manganese, copper, cobalt or nickel soap.[13]

Morrell and Egloff[14] suggest that sulphur dioxide and oxygen be mixed and used in the treatment of cracked distillates. These investigators treated a cracked California distillate with 4 pounds of sulphur dioxide per barrel, a slight excess of oxygen over that required to oxidize the sulphur dioxide, and about 2 pounds of steam per barrel. Temperatures of 120 to 315°C. are recommended in this treatment, and the vapors are contacted with solid catalysts such as clay, or with a finely divided metallic salt (e.g., zinc sulphate) on a support of fuller's earth. Under such conditions, the distillate showed a reduction in sulphur content of from 0.25 per cent to 0.1 per cent. These investigators have also suggested using oxygen and phosphoric acid in the presence of a non-metallic contact agent such as fuller's earth for removing sulphur.[15]

Harris[16] reports removing the haze-forming constituents of lubricating oils by an oxidation process. The oils are treated with air at 150 to 260°C. for a time sufficient to oxidize about 5 per cent of the oil. The product of this treatment is then dewaxed in the usual manner.[17]

Oxygen is used in some refining processes to revivify the refining agent. Peterkin[18] suggests, for instance, that if cupric chloride, lead sulphide or mercuric chloride is used as the refining agent, the catalyst can be revivified by treatment with air. Peck and Kleiber[19] have proposed a refining method involving two cracking zones. In the first of these, an oil stream is conducted through a pipe which is externally heated to a temperature of approximately 455°C. At this temperature, the oil is maintained under superatmospheric pressure, and no substantial decomposition of the hydrocarbons occurs. In the second zone, preheated oxygen or air is introduced into the heated oil. Partial combustion ensues, which rapidly raises the temperature of the material to 500-600°C. Thus, a Mid-Continent gas oil was heated to approximately 455°C., when about 3 per cent cracking to gasoline took place. At this point, air preheated to 455°C. was introduced into the oil in the ratio of approximately 15 cubic feet of air per gallon of oil. The partial combustion of the oil raised the temperature to about 540°C. A 30 per cent conversion to gasoline of good antiknock rating was reported. It is said that this method of cracking reduced the loss to gases and tar by about 50 per cent.

Kirsanov and Suslina[20] have studied the effect of ozone on gasolines from Chusov crudes. They report that by ozonization a practically sulphur-free gasoline can be obtained. The best results were procured when the ozonized product was distilled over lime in the presence of steam. The ozonization was conducted at −20°C., at which temperature the sulphur compounds are said to be converted into sulphuric acid, acidic non-volatile products, and neutral non-volatile compounds. The investigators report that ozonization tends simultaneously to lower the iodine number, however, and increase the paraffin and aromatic content at the expense of the naphthenes. From the desulphurization curves obtained, it appeared that the gasoline contained three general types of sulphur compounds reacting with the ozone at different rates. They believed that the sulphur compounds were largely derivatives of naphthenes and aromatics. It was suggested that an approximate picture of the number and type of substances contained in the mixture could be deduced from the desulphurization curves obtained in this ozonization. Morrell and Egloff[21] report a desulphurization process employing ozone. They suggest that the hydrocarbon vapors to be treated be passed over a bed of finely divided contact material such as sand, clay, fuller's earth or inert silicates together with a small amount of ozone (ten cubic feet of ozonized air per barrel of condensed hydrocarbon). At the same time, an alkaline solution (e.g., sodium plumbite, zincate or aluminate) runs countercurrently to the gases.

---

[12] L. P. Chebotar, U. S. P. 2,036,396, April 7, 1936, to Texas Co.; *Chem. Abs.*, 1936, **30**, 3626; *J. Inst. Pet. Tech.*, 1936, **22**, 266A.

[13] The sulphur content of hydrocarbon gases used in bright-annealing furnaces can be removed by oxidation. (See, for example, A. G. Lobley, (British P. 429,402, 1935, to Birmingham Electric Furnaces Ltd.; *Brit. Chem. Abs.* **B**, 1935, 955; *Chem. Abs.*, 1935, **29**, 7267.) In this case the gases are mixed with sufficient air to burn the sulphur to sulphur dioxide and hydrogen sulphide, the gases are cooled, and the sulphur dioxide and hydrogen sulphide permitted to react to precipitate sulphur. The partly purified gases are then passed over an absorbent (calcium oxide or sodium carbonate) to remove the excess of sulphur dioxide.

Darrah[22] has made the suggestion that hydrocarbon oils be treated with oxygen in a type of electrolytic cell wherein the electric current supplies both the oxygen, and by the resistance to its flow, the heat needed in the transformation. The oil (kerosene or fuel oil) is suspended in an electrolyte, such as a soap solution and passed through a restricted opening. An electric current of relatively high density is passed through the solution at this point, strongly heating the liquid and at the same time releasing oxygen for the formation of oxidation products.

OXIDIZED MOTOR FUELS

Ellis[23] has found that gas oil, cracked and subsequently oxidized, may be made to yield a gasoline of high antiknock value. In this process, the oil is first cracked (at about 400°C.) under 250 to 350 pounds per square inch pressure and transferred to a "soaking tank" maintained at a similar temperature. The hot, cracked vapors from this tank are passed to an oxidizing chamber, where oxygen is admitted at a number of points but in quantities sufficiently small so as to prevent the formation of an explosive mixture (sufficient only to oxidize 5 to 10 per cent of the hydrocarbon vapors). The reaction may be carried out in part, he finds, by admitting a small part of the oxygen to the "soaking tank." This is not as satisfactory as oxidation in the separate reactor, however, since the temperature and other conditions in this part of the apparatus are determined as best for cracking reactions rather than oxidation. The oxidation reactor is best maintained at a temperature of 120° to 240°C. From the oxidized products, a gasoline fraction is obtained. This distillate may include higher ends than are ordinarily permissible, due to the high antiknock rating resulting from the partial oxidation. Cracked gasoline consists essentially of a complex mixture of paraffinic, olefinic, aromatic and naphthenic compounds. Of these, olefins tend to carbon deposition upon combustion, and aromatics effect a suppression of the knocking tendencies of the fuel. Ellis[23a] proposes to oxidize olefinic and dehydrogenate naphthenic compounds in a single operation by treating distillation vapors from cracked gas oil with air. During the period of contact of the hydrocarbon vapors and air, the temperature of the reactants is held at 205-215°C. and the pressure at 3-4 atmospheres. Thus a fuel containing a large proportion of aromatics and a small percentage of olefins is said to be secured.

[23a] Carleton Ellis, U. S. P. 2,077,994, April 20, 1937, to Ellis-Foster Co.; *Chem. Abs.*, 1937, **31**, 4104.

Burk and Hughes[24] have suggested that the antiknock value of fuel may be increased by treating a straight-run gasoline at 450 to 700°C. in the presence of ½ to 5 volumes of air per volume of gasoline vapor, for 0.075 to 1 second under 100 pounds per square inch pressure. If the conditions are held close to 500°C. with a contact time of 0.7 seconds and an air-to-fuel ratio of approximately 1:1 used, the conversion is said to take place without substantial change of the boiling point characteristics.

It has been found that a naphtha of unsatisfactory knock rating can be blended with a cracking-coil tar and treated with oxygen to produce a satisfactory motor fuel. Burk[25] reports that the hydrocarbon tar, too heavy for use as a motor fuel, will react with oxygen and the lighter hydrocarbon material if the two hydrocarbon mixtures are preheated to 370° to 600°C. and then subjected to the action of a controlled amount of oxygen. The reaction is carried out under 10 to 150 pounds per square inch pressure. An analogous process has been suggested by this investigator for producing motor fuel from gas oils. The hydrocarbon is heated to a cracking temperature while under pressure in a pipe or coil. The pressure is then released, and the hydrocarbon is atomized in the presence of air while at a temperature of 600°C. The contact with air lasts from 1.5 to 25 seconds, and a pressure of 10 pounds per square inch is maintained in this reactor to effect the conversion into motor fuel. It is also possible to lower the boiling point of hydrocarbon materials by an oxidation process. Thus Ellis[26] has described a process of preparing an oxidized kerosene or gasoline from a heavier fuel. The raw material (e.g., kerosene) is passed through a cracking tube heated to 540° to 590°C. and thence to a trap, wherein the very heavy products are removed. The vapors and fixed gases then pass into a mixing chamber, where they are mixed with air. The mixture of oil vapors and air is then passed over a catalyst of pumice fragments impregnated with vanadium oxide. This catalyzer is contained in a U-tube of sheet steel, immersed in a bath of molten lead. The temperature of the lead bath is held at 425° to 430°C. The resulting vapors are passed first through a water scrubber, then an oil scrubber, and finally over silica gel. The oxidized material so obtained is blended with pressure-still or natural gasoline, or a blend of the three is prepared for use as an antiknock motor fuel.

A process suggested by Chappell[27] also combines the lowering of boiling point with increase of antiknock value. The oil is heated to a cracking temperature (425° to 700°C.), under pressure (up to 1000 pounds per square inch), and passed into a reaction chamber. Unvaporized oil is withdrawn from this chamber, and oxygen-containing gas (air), preheated to the temperature of the oil, is admitted. The amount of oxygen admitted is so regulated as to reduce the hydrogen content of the oil vapor to approximately 14.3 per cent. The reaction products are fractionated and a motor-fuel fraction obtained which is reported to have a high antiknock value. The unvaporized oil and the higher oxidized fractions are blended to produce a heavy fuel oil.

The oxygen required for the partially oxidized motor fuels may, it is reported, be supplied by substances other than air. Thus, a mixture of heavy crude oil, 2 per cent of chromic acid mixture, and half of 1 per cent of a catalyst such as manganese dioxide or barium peroxide, may be agitated together and allowed to stand. After 24 hours, the upper, clear solution is decanted from the precipitate and used as a substitute for gasoline.[28]

James and Zeisenheim[29] studied the properties of some oxidized fuels (kerosene and gasoline) of this type and report that, although the gross thermal value of the oxidized material is about one-eighth less than that of the hydrocarbon from which it derived, other factors may offset this. They believe, however, that greater energy is available in an internal combustion engine powered by these fuels. This paradoxical result was due, they suggest, to the fuel molecules being weakened to oxidation attack (in the internal combustion engine) because of their oxidized character. This is considered to result in a better "clean up" and more propulsive effort during combustion.

Oxidation of still vapors from a cracked oil results in the formation, in addition to partially oxidized gasoline, of acids and aldehydes which may impart an objectionable odor to the fuel. Removal of these constituents may be brought about by hydrogenation, polymerization, or by the addition of phenols to form synthetic resins.[29a] In one procedure, kerosene was allowed to drip into a cracking furnace at 1200-1300°F. The cracked vapors issuing from the furnace were partially condensed to separate the heavier portions. Uncondensed vapors and air were then admixed and led into a reaction chamber containing a promoter of iron coated with vanadium oxide. Oxidation was effected at 800-1000°F., and the liquid products collected by condensation. The latter consisted of two layers, the upper containing oxidized gasoline, the lower an aqueous solution of acids and aldehydes. Phenol was then incorporated in the aqueous layer together with a condensation catalyst to furnish a synthetic resin.

PRODUCING FUEL GAS FROM HYDROCARBON OILS

Some years ago[30] (1913) it was proposed that a fuel vapor for use in an internal combustion engine might be prepared by forcing a jet of a hydrocarbon oil such as kerosene through a flame. The finely divided fuel is simultaneously raised to a high cracking temperature and partially oxidized, and these resultant vapors collected. It is said that the vapors so produced are well suited to rapid or instantaneous combustion, and do not deposit carbon in the engine consuming them. The apparatus is so designed that the flame is unable to strike back along the fuel vapors by reason of metal screens which rapidly lower the temperature of the vapors below the ignition point. The apparatus is maintained at less than atmospheric pressure by the intake manifold vacuum of the associated engine. At intermediate points between the cracking and oxidizing flame and the internal combustion engine, but beyond the point where the flame is effectively extinguished, heated air is introduced. The fuel vapor so produced is relatively persistent, being composed largely of permanent gases, and though it cannot be stored or piped long distances, it is sufficiently stable that it may be piped, for instance, across a yard or across a street. In contrast, however, Perry[31] reports that a commercially distributable gas may be produced by an oxidation-cracking process. This process uses refinery gases as raw material, however, conducting gases and oxygen in separate streams to a reaction zone. The oxygen is introduced into the center of the stream of hydrocarbon gas in such a manner that it is completely surrounded by the oil gases. Partial combustion ensues, the intense heat of the oxidation serving to crack the remainder of the hydrocarbon. The combustion takes place in an enclosed chamber, and the resulting products are said to form a gas mixture having specific density and calorific power closely approximating those of carbureted water-gas.

An analogous process for making an internal combustion engine fuel from even heavier hydrocarbons was suggested by E. B. Benham (U. S. P. 1,000,768, Aug. 15, 1911, to Hydrocarbon Converter Co.; *Chem. Abs.*, 1911, **5**, *3727*) who proposes a system of heated contact zones. The hydrocarbon oil (a crude from which the lighter fractions have previously been removed) is injected with a stream of air into a reaction chamber made of clay or siliceous material. The fuel droplets impinge on a refractory surface at a temperature of 600° to 800°C., the partial combustion of the hydrocarbon aiding in maintaining this temperature. The cracked vapors are then led through a further high temperature zone that the cracked molecules may become stabilized. In this apparatus, too, the vacuum created by the internal combustion engine aids the circulation of the vapors. In starting the apparatus, and as an aid in maintaining the high temperatures required, the hot exhaust gases of the internal combustion engine are circulated about the cracking apparatus. The engine is started on gasoline originally.

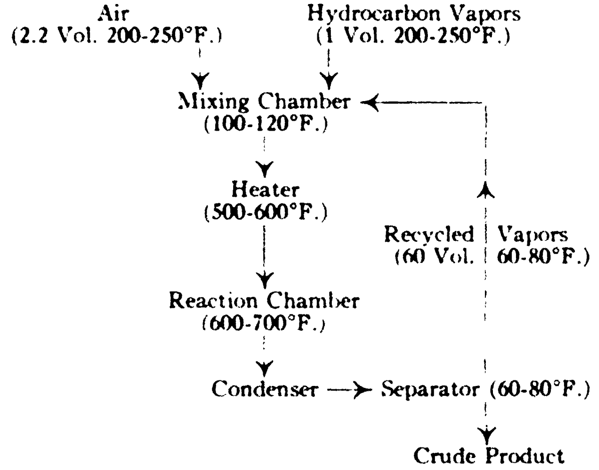

FIG. 250A. Flow Diagram for Controlled Oxidation of Gaseous Hydrocarbons to Alcohols and Other Oxygenated Products. (C. L. Thompson, T. S. Bacon and J. E. Bludworth)

If a hydrocarbon oil is burned with a limited supply of oxygen and under proper conditions, a mixture of carbon monoxide and hydrogen is obtained, it is reported. The temperature of this reaction, of course highly exothermic in nature, can be controlled, however, by the addition of a regulated supply of steam to the entering gases, along with a further quantity of oil. The reaction ensuing between the oil and water vapors at the high temperature produces further carbon monoxide and hydrogen by an endothermic reaction. The resultant mixture is, finally, practically pure carbon monoxide and hydrogen. This product may be enriched by the addition of hydrocarbon illuminants if it is desired as a general fuel gas.[32] Maier[33] points out that such mixtures of hydrogen and carbon monoxide can be made also by non-inflammatory reaction if a catalyst is employed and high gas velocities maintained. He suggests, for example, that a properly proportioned hydrocarbon-oxygen mixture be passed over a catalyst of nickel on aluminum oxide maintained at a sufficiently high temperature to initiate the reaction. The gases pass

[33] C. G. Maier, U. S. P. 2,039,603, May 5, 1936, to Mountain Copper Co., Ltd.; *Chem. Abs.*, 1936, **30**, 4278.

over the catalyst at a velocity sufficient to prevent flame. This velocity falls gradually, although it is always great enough to prevent inflammation. The product gases are reported to be substantially free of carbon dioxide, water vapor and unreacted hydrocarbon. This investigator[34] suggests that an apparatus for the oxidation be arranged in such a manner that a high velocity stream of preheated air picks up a side stream of hydrocarbon gas, and the mixture passes into a catalyst chamber. This chamber contains a porous catalytic mass, and is parabolic in shape, allowing the gases to expand as they pass through. The stream of gas on entering the catalyst is deflected by a crucible-shaped, non-porous baffle. Ray[35] has suggested a catalytic method for removing unreacted oxygen from large volumes of gas, wherein the oxygen constitutes less than 4 per cent of the composition. The gas mixture is brought in contact with a highly reactive mass of carbon kept at a temperature of approximately 600°C. for a short, regulated time. The time of contact is controlled to allow the reaction of the oxygen with the carbon to form only carbon monoxide. Walker,[36] on the other hand, proposes a method for accomplishing removal of small percentages of oxygen from large volumes of gas which involves the addition of further oxygen as the first step. The amount of oxygen to be added is determined by the amount already present; the total amount is fixed by the reaction conditions to be maintained. The total amount is to be such that when passed over a catalyst (platinum, manganese dioxide or cupric oxide) at a high temperature, reaction shall ensue, consuming all the oxygen present and liberating sufficient heat of combustion to maintain the catalyst at the desired temperature.

PRODUCTION OF ALCOHOLS AND ACIDS

The production of hydrogen and carbon monoxide by oxidation of hydrocarbon oils and gases is of growing importance in the production of methyl alcohol, produced synthetically by the condensation of these two gases. This type of synthesis will be discussed under the reactions of carbon monoxide and is beyond the scope of the present chapter.[36a] The reaction of oxygen with the lighter hydrocarbons of refinery gases has been found to produce considerable quantities of methanol, accompanied, however, by other and more completely oxidized products. It has been proposed that a mixture be prepared consisting of 0.5 to 3 per cent oxygen (by the addition of the corresponding volume of air), 10 to 40 per cent refinery gases, and sufficient exhaust gases from the process to make up 100 per cent. This mixture is heated to about 370°C. under 250 pounds per square inch pressure. These conditions are maintained for a sufficient period of time to permit complete combination of the oxygen, and the resulting vapors are then cooled. The uncondensed portions are recirculated in the process chambers.[37] Cristescu[38] reported a method whereby methane and carbon monoxide or dioxide might be reacted to produce alcohols. The mixed gases are passed through boiling water containing a catalyst, such as wood charcoal and a metal oxide (e.g., cupric oxide, lead dioxide or zinc oxide). The resulting gases are then passed through a reaction chamber containing a further catalyst of wood charcoal washed with sodium hydroxide.

On the other hand, Penniman[39] has reported making higher alcohols, aldehydes, ketones and other similar oxidized products by a direct oxidation of residual oils from cracking stills. In this process a stream of the hydrocarbon is preheated to 150°-370°C. and passed into a converting vessel under pressure substantially greater than atmospheric. Air is admitted to this chamber, and the partial combustion maintains a temperature here of approximately 400°C. The resultant vapors are removed and the less volatile constituents returned to the reaction zone. Preheating of these liquids is unnecessary. The vapors are fractionated to recover motor fuels and the mixed oxidized compounds, largely alcohols, ketones and aldehydes of higher molecular weight.

Carpenter[40] reports a further carbon monoxide reaction of the lower alcohols, such as methanol, by which the next higher aliphatic acid is produced. Methanol and carbon monoxide are reacted in the presence of a catalyst such as chromic or tungstic acid, under 700 atmospheres pressure and at a temperature of 300°C. The carbonyl group adds to the molecule, producing acetic acid. Woodhouse[41] reports an analogous reaction, involving the treatment of methyl alcohol and carbon monoxide in the presence of silicon, magnesium, aluminum, titanium, zirconium or tungsten oxides or their mixtures. Similar conditions are used (i.e., 700 atmospheres pressure at 300°C.), but under the influence of these catalysts, other compounds such as methyl formate and methyl acetate are formed, as well as acetic acid. The process has been investigated by a number of workers and various catalysts proposed. Some recommend the addition of a diluent such as nitrogen or water vapor to the reactive vapors. Inorganic polybasic acids (e.g., phosphoric and arsenic acids) have been suggested as catalysts[42] as well as a complex silica-phosphate $[SiO(PO_3)_2]$ which can be revived by the action of phosphoric acid.[42a] Woodhouse[43] reports that halogens, hydrohalides, alkyl halides and nitrogen oxides serve as accelerators in such reactions as that producing acetic acid from methyl alcohol and carbon monoxide and in a number of other reactions involving carbon monoxide.

A different type of reaction producing acids from alcohols has been proposed by Hale.[44] This reaction involves dehydrogenation of the alcohol with the intermediate formation of the corresponding aldehyde, and the subsequent addition of a molecule of water to form a dihydroxy compound. In the presence of a basic salt of an amphoteric salt-forming metal and an organic acid (i.e., such a salt as hydroxy manganese acetate,  $HOMnO\underset{\underset{O}{\|}}{C}\text{-}CH_3$) the dihydroxy compound reacts to form the diacetate and water. The series of reactions, then, is as follows:

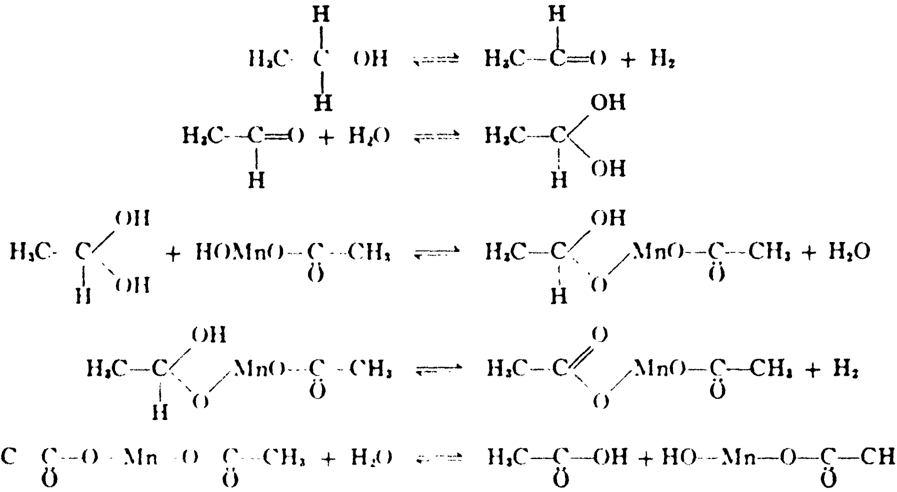
[44] W. J. Hale, U. S. P. 2,027,378, Jan. 14, 1936; *Chem. Abs.*, 1936, **30**, 1384.



In summation of the five sets of equilibria, one molecule of alcohol plus two molecules of water yield one molecule of acid, one molecule of water and two molecules of hydrogen. Theoretical 100 per cent efficiency would reduce this to an interaction of one molecule of water and one molecule of alcohol to yield one molecule of acid and two of hydrogen, the water serving as the oxidizing agent.

The catalyst employed must be a salt of a metal capable of forming amphoteric hydroxides, reacting with organic acids to yield basic salts which resist complete hydrolysis under the action of water at a temperature of 350°C. At the same time, a dehydrogenating catalyst must be present, and the presence of free hydrogen must not reduce the amphoteric metal oxide to the free metal. These conditions so limit the choice of metals, Hale states, that only beryllium, copper, magnesium, zinc, aluminum, zirconium, the cerium metals, chromium, manganese, iron and cobalt compounds reacted satisfactorily. Of these, the basic salts of iron, cobalt, copper and zinc were limited to relatively low temperature conditions, owing to the high hydrogen concentrations obtained. The dehydrogenating catalyst to be incorporated in the catalyst mass may consist of metallic copper, silver, zinc, palladium, or other platinum metals.

The concentration of hydrogen resulting from the reaction should be removed, Hale finds, in order to prevent its tendency to reverse the equilibrium. This may be accomplished, he suggests, by the use of a membrane selectively porous to hydrogen, such as a thimble of sillimanite. The temperature conditions maintained may lie between 150° and 350°C., but optimum results were obtained at 260° to 280°C. The primary reaction of dehydrogenation is endothermic, however, and the fore part of the reaction tube may advantageously be maintained at a somewhat higher temperature than the after section. Thus, using 46 grams (one mole) of ethanol, and 2 moles of water over a catalyst composed of copper, manganous and aluminum salts and copper metal at an entering temperature of 300°C. and an efflux temperature of 260° to 280°C., the following results were obtained:

Product	Grams
Acetic Acid (52.6% concentration)	30
Acetaldehyde	21.5
Ethyl Acetate	0.3
Hydrogen	3.0
Water	27.0

By recycling the acetaldehyde fraction, the concentration of acetic acid was raised to 75 per cent.

This process is said to be advantageous in that it yields a product containing concentrated acid, and, during the oxidation, no explosive mixture is formed. It may be applied equally to ethylene, or higher homologs, or higher alcohols such as butanol.

A cyclic method of producing the corresponding acid from one of the lower alcohols suggested by Hale and Haldeman[45] produces the aldehyde as an intermediate step. In this process, the alcohol (e.g., ethanol) is passed over a dehydrogenating catalyst to form the corresponding aldehyde and free hydrogen.

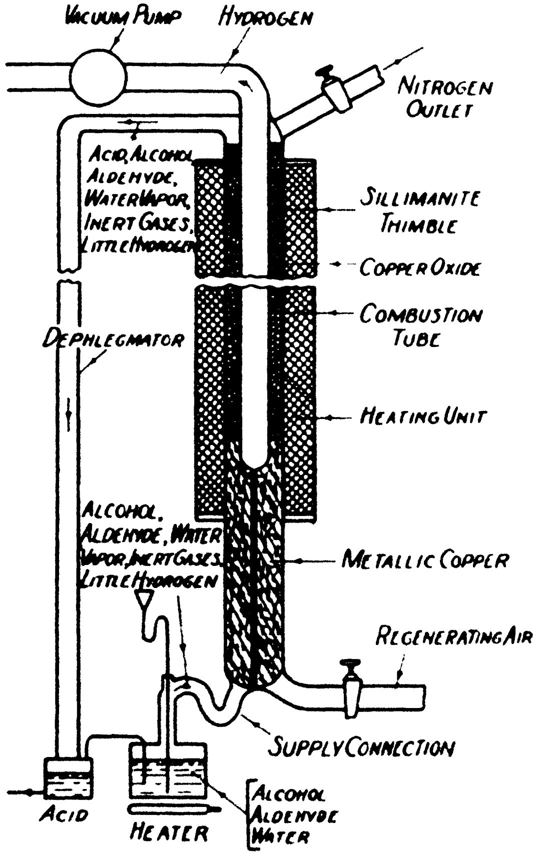


FIG. 251. Sketch of Apparatus for Oxidation of Alcohols to Aliphatic Acids. (W. J. Hale and W. S. Haldeman)

The reaction mixture is then passed over a surface made of a material such as sillimanite which is permeable to hydrogen, and part of the hydrogen is separated in this way. The mixed aldehyde-containing vapors then contact a readily reducible oxide, such as cupric oxide, at a temperature between 150° and 350°C., and are oxidized to the corresponding acid and water. The acid is separated from the mixed products, the remaining vapors mixed with further alcohol, and the mixture recycled through the system (See Fig. 251).

---

[45] W. J. Hale and W. S. Haldeman, U. S. P. 1,951,280, March 13, 1934; *Chem. Abs.*, 1934, **28**, 3416; *Brit. Chem. Abs.* **B**, 1935, 138.

It is frequently found that the recovery of petroleum oxidation intermediates in fair degree of purity is difficult, and this property can be used to advantage in the production of alcohol denaturants. James[46] suggests that a liquid hydrocarbon be vaporized, mixed with air and passed through a contact zone at a temperature of 180° to 500°C. The contact catalysts employed are oxides of metals having variable valency, such as the blue oxides of molybdenum. The vaporous products are condensed, yielding a complex liquid mixture of partial oxidation products ranging from alcohols through aldehydes to aldo-fatty acids. The percentage of the various chemical substances composing the final mixture may be varied by control of such conditions as the reaction temperature, time of contact, and whether or not steam or other diluent is added to the gases before reaction. James reports that alcohols, aldo-alcohols, aldehydes, ketones, aldo-acids, aldo-hydroxy acids, keto-acids, hydroxyketo-acids, and mixed esters of these compounds, both normal esters and lactonic-type esters, are present in the condensed product. In addition there are present ethers, both of the normal type and of the inner or "bridge" type. Some unchanged hydrocarbons pass through, as well as fractions consisting largely of highly unsaturated compounds possessed of persistent and penetrating odors. This complex mixture is neutralized by the addition of either caustic alkali or a lime slurry, and the neutral product remaining extracted with alcohol. The alcohol is said to selectively dissolve out the more highly oxidized constituents of the mixture, and by regulating the amount of water incorporated with the alcohol, effective separation of two liquid layers is secured. A distillation step separates a portion of the oxidized mixture having a distillation curve close to that of alcohol, resulting in a denaturant which, it is said, cannot be removed from the alcohol by chemical or physical means short of the destruction of the alcohol.

That effective denaturants difficult to separate from the denatured substance can be produced from partially oxidized hydrocarbons indicates the complexity of the problem facing the investigator who seeks to derive pure compounds by this partial oxidation. Primarily, the problem is naturally somewhat simplified by so choosing conditions of reaction as to minimize the formation of these complex mixtures rather than to favor them. Numerous methods of separation have been suggested, however, such as the solvent extraction suggested by James.[47] He reports that the more highly oxidized products can be separated from the less oxygenated substances (in the range of alcohols to organic acids) by an extraction with liquid sulphur dioxide. Thus the partial oxidation products of a hydrocarbon fraction such as gasoline may be condensed and the cooled liquid treated with liquid sulphur dioxide. The fractional extraction is controlled by the temperature (always below the boiling point of the sulphur dioxide extraction agent) at which the process is carried out.

SOLVENTS, DRYING OILS AND VARNISHES

The partial oxidation products of light hydrocarbon distillates have been suggested as solvents for various uses, but James[48] finds that these frequently have powerful, and usually objectionable, odors due in large part to various aldehydic compounds. He reports that this odor can be largely eliminated by a treatment with alcohol and calcium chloride. The addition of these materials in anhydrous form brings about a condensation of the odoriferous aldehydes to less pungent acetals. These, in turn, can be extracted with 70 per cent ethyl alcohol which acts as a selective solvent for the more highly oxidized components of such a complex mixture to leave a solvent which is said to be almost odorless.

[48] J. H. James, U. S. P. 1,907,822, May 9, 1933, to C. P. Byrnes; *Brit. Chem. Abs.* **B**, 1934, **86**; *Chem. Abs.*, 1933, **27**, 3761.

Instead of oxidizing the lower hydrocarbons to liquid compounds it has also been suggested that the higher hydrocarbons such as paraffin wax may be oxidized to produce esters suitable for use as plasticizing and softening agents for plastics containing cellulose derivatives and lacquers of this type. In this procedure paraffin wax is oxidized by nitric acid at 90°C., the concentration of nitric acid being maintained by adding gaseous nitric anhydrides. The oxidation product is esterified with butyl alcohol and the ester distilled off (at 170° to 230°C. under 1 or 2 mm. pressure). It is reported that if this ester is added to a solution of low-viscosity cellulose nitrate in a butyl acetate-butyl alcohol-toluene solvent, a lacquer yielding a durable film is formed.[49] Winning[50] suggests that a solvent be prepared by the partial oxidation of a "hydroformed solvent" (a product derived from the destructive hydrogenation of a petroleum fraction boiling in the gasoline range and up to 370°C.). Thus, a cracked hydrocarbon distillate boiling between 224° and 332°C. was obtained from a Mid-Continent crude. It was destructively hydrogenated at 510°C. under a pressure of 3000 pounds per square inch. A fraction of the product boiling below 200°C. was separated, and the remainder recycled. The material so obtained, was placed in a glass-lined bomb under 110 pounds pressure of air, and held at a temperature of 100°C. for 48 hours. The resulting oxidized product was reported to be an effective substitute for aromatic solvents such as benzene or toluene in preparing surface coatings.

That drying oils of various sorts could be made by partial oxidation of petroleum fractions has been known for some years. In 1867 DeGerbeth[51] reported making a drying oil suitable for paint and varnish making or oil-cloth production by oxidizing petroleum oils. In this process, 25 to 40 gallons of water were mixed with each ton of oil, and the whole blown with steam until reaching a temperature of 80° to 100°C. Oxidation was then brought about by the addition of hypohalites, perhalates or manganese dioxide. Agitation with steam and a drying agent was continued. Finally, the mixture was blown with air or ozonized air.

Woods[52] commented on the resemblance of the gums formed in cracked gasoline to linseed oil, and suggested that a drying oil could be made by oxidizing a vapor phase cracked Mid-Continent gas oil. A naphtha fraction boiling between 48° and 225°C. was oxidized for six hours at 100°C. under 100 pounds per square inch pressure of air. The sample was cooled, and distilled under vacuum to 6 per cent bottoms. The resemblance between the drying oil so prepared and commercial linseed oil was shown by the properties listed in Table 203.

TABLE 203. *Comparison of Natural and Synthetic Drying Oils.*

	Commercial Linseed Oil	Drying Oil from Cracked Gasoline
Gravity °A.P.I.	19.8	21.4
Iodine No.	186	180
Saponification No.	190	188

The two oils were compared as thinners in paints for use on both metal and wood surfaces. After 12 months exposure, the paint made with the oxidized cracked naphtha showed signs of cracking, however. The investigator believes that the proper treatment may be found which will produce a satisfactory oil, at considerable economic advantage.

[52] G. M. Woods, *Petroleum Engineer*, 1936, **8**, No. 1, 106.

Pohl[53] described a process for producing driers for use in varnishes, lacquers and paints consisting essentially of heavy-metal water-insoluble soaps. These products are made by treating the mixed oxidation products of paraffin wax, or a similar wax, with cobalt acetate (at 100° to 140°C.) or with caustic soda solution. If the soda solution is used, the resultant soap is separated from unsaponifiable substances, and the organic radical precipitated by treatment (at an elevated temperature) with a metallic salt of an inorganic acid, such as manganous chloride, copper sulphate or aluminum sulphate. Fiore[54] reports producing a paint vehicle oil by oxidizing a mixture consisting of 80 per cent mineral oil and 20 per cent vegetable oil by passing ozone through the mixture (maintained at 100°C.) for 1 hour. The process is completed by adding a quantity of a 1:2 mixture of nitric acid and ethyl alcohol equal to about one-half the weight of the oil mixture. Instead of using an oxidized petroleum oil directly, Adal'yan[55] has found that the acid sludge produced in refining processes can be treated to procure a drying oil. The sludge is diluted with water and thoroughly agitated with air, the upper layer then being separated. It is agitated several times with water and neutralized with sodium hydroxide. The final product is reported to dry in 3 to 4 hours, forming a thin, elastic film.

It is reported that pentaerythritol esters of the acids obtained by oxidation of paraffin wax are useful in the preparation of varnishes. The esters are prepared by heating the oxidized paraffin acid (in the presence of catalysts) with pentaerythritol. Basic oxides or hydroxides, such as lead monoxide, calcium, or zinc oxide or sodium hydroxide, serve as catalysts. Inert diluents (e.g., nitrogen or carbon dioxide) may be present as well.[55a]

LUBRICATING OILS AND GREASES

King[56] has pointed out that an oil which has been oxidized may have greatly increased film strength. For instance, an oil capable of maintaining a film intact up to 160°C. in its ordinary state may, after oxidation, prove capable of maintaining lubrication up to 300°C. He offers the explanation that these oxidized oil molecules attach themselves to the lubricated metal surfaces by the oxidized, and hence activated, end. It has been shown that normal oil loses to some extent its "oiliness" (its ability to resist film-rupture) if run through clean glass or silica chips, since the polar substances which have the greatest power of gripping surfaces are left behind. Oil, so treated, regains its "oiliness," however, if left in contact with the air. On the other hand, in contact with nitrogen this recovery does not occur. It appears that the oxidized oil molecules have not only greater adhering strength, but their coherence is greater as well. Thus, the suggestion is made that on the first polar attachment to the lubricated metal a layer of coherent polar lubricant many molecules thick is built up. This condition would result in diminished rigidity, increased slip, and hence lower friction.

However, King reported that single-variety oils were able to show little improvement on oxidation. Blended oils (i.e., oils of different oxidation characteristics) increased in viscosity or maintained viscosity over long periods of oxidation, and their performance showed sustained improvement. The most satisfactory results were obtained with blends of easily oxidized varieties and those difficult to oxidize. Oxidation was then assumed to take place through the influence of the readily oxidized molecules.

It has been suggested[57] that a lubricant for use under extreme pressures may be manufactured by incorporating esterified oxidized paraffin alcohols in a high quality lubricating oil stock. The esters formed by combination of alcohols heavier than decyl alcohol with lower acids (such as mixed acetates from the oxidation of hydrocarbon wax) are particularly mentioned. MacKenzie[58] has suggested that the addition of 2 to 5 per cent of oxidized paraffin wax to a low viscosity (37 to 60 seconds Saybolt at 100° F.) oil will render it suitable for use on heavy machinery.

An oxygen polymerization product has been reported by Davis[59] which is said to improve heavy, waxy oils. This material is prepared from liquid hydrocarbons (of 10 or more carbon atoms) by low temperature oxidation treatment in the presence of a siccative. The substances formed are largely alcohols, aldehydes, ketones and esters. James[60] treats a light lubricating oil by a vapor-phase catalytic oxidation, and fractionally distils the product. The heavier ends are treated with relatively small amounts of sulphuric acid at a temperature materially above 45°C. Excess free sulphuric acid is removed, and the oil-soluble sulphonates extracted, leaving a lubricant considered to be substantially free of gum-forming constituents. The product can be used in conjunction with either engine lubricating oils or with gasoline as an overhead engine valve lubricant.

PRODUCTION OF WAXES

A partial oxidation of petrolatum can be made to yield a series of low boiling oils and a paraffin, according to Zieley.[61] The petrolatum to be treated is atomized by superheated steam and the mixture passed into a tower into which air and further superheated steam are injected at the bottom. The temperature in the reaction zone is held at about 540°C., while a pressure of 60 to 70 pounds per square inch is maintained. The condensed products of the reaction yield a paraffin and oils of oxygenated character. On the other hand it has been suggested that the oxidation products of high molecular weight hydrocarbons be heated with fats, fish oils or their derivatives. A decarboxylating catalyst is added, and the resulting condensation products are reported to be waxes suitable for polishes, sizing and impregnating agents for textiles.[62] A wax useful in preparation of shoe polishes, paper-coating materials and polishes is said to result from an esterified bleached montan wax. The bleached wax is oxidized to convert it more completely into fatty acids, and these acids are reduced to the corresponding alcohols. The resulting alcohols are then esterified with monocarboxylic acids of 10 to 25 carbon atoms, such as stearic, palmitic or linoleic acid. The physical properties (e.g., hardness) of the resulting waxy substances may be controlled by the choice of acids with which the alcohols are esterified.[63] For the production of bleached montan wax, Pungs and associates[64] suggest that the wax be first saponified and the resulting fatty acids and alcohols separated. The alcohols are bleached by a solid adsorbent, such as activated carbon, and the acids are separately treated with an oxidizing solution such as potassium bichromate and sulphuric acid. The bleached substances are then re-esterified, and by controlling the proportions of acids and alcohols used or by adding other alcohols or acids, the properties of the wax may be modified. According to Labarthe and Tressler,[65] a beeswax substitute melting at a temperature of about 75°C., or only 10° higher than the natural substance, can be made by oxidation of high-melting paraffin hydrocarbons such as "Superla" paraffin wax, melting at about 60°C. or higher, or from Utah wax (derived from Utah ozokerite). Both of these waxes are purely hydrocarbon materials, consisting almost entirely of straight- or branched-chain compounds, and have acid and ester values of practically zero. The oxidation process is carried out at a temperature between 120° and 150°C. if oxygen is used, and at a somewhat higher temperature if air is the oxidizing agent. Finely divided nickel or manganese metal or their oxides or soaps serve as catalysts in this reaction, the manganese compounds being perhaps more desirable in that they produce a lighter colored product. It is advantageous to use oxygen rather than air, since the lower temperature of the reaction under the influence of oxygen lessens decomposition of the products. Thus, in one example, 1500 g. of ozokerite wax were mixed with 15 g. of manganese oleate and maintained at 120°C. while dry oxygen was bubbled through the molten mix for 288 hours. The exhaust gases from this reaction were passed in a similar manner through a second mass of ozokerite wax and manganese oleate. At the end of the reaction time, the acid value of the first mix had risen to 25.8 and the ester value to about 50.6, while the material in the second reactor flask showed acid value of 46.7 and ester value of 56.6. The results appear to indicate, the investigators believe, that considerable proportions of high molecular weight alcohols, aldehydes and acids are formed and possibly some heavy ketones, as well.

Oxidized waxes have been suggested as substances useful in improving the adhesive properties of road bitumen, particularly in the presence of water. The addition of 0.1 to 2 per cent of oxidized paraffin wax materials is said to make bituminous road oils hold the aggregate materials more firmly.[66] Oxidized montan or carnauba wax is capable of acting as a vehicle or adherent in preparing wax-impregnated ceramics or wax-coated metallic vessels, according to Sommer, Weissbach and Reinhardt.[67] The waxy products obtained by the oxidation of montan wax are mixed with paraffin, ceresin or ozokerite wax and applied to the stock to be treated. The resultant walls are reported to be impervious to acids.

MISCELLANEOUS OXIDATION PRODUCTS

Resins. Industrially useful resins may be prepared by the oxidation of petroleum fractions, or by treatment of the oxidation products obtained from petroleum fractions.[68] Thus, treatment of a gasoline fraction with air or oxygen may furnish a synthetic resin, Borst[69] reports. In the process he proposed, a Mid-Continent residuum was pyrolyzed to yield a cracked gasoline boiling between 40° and 220°C. This material was placed in a pressure vessel provided with an inlet spray line. The vessel was heated to approximately 150°C. and a mixture of about equal parts of air and oxygen was introduced until about 3 pounds of gummy material was produced per gallon of original gasoline. The pressure apparatus was then cooled and opened. The remaining hydrocarbon was decanted, and a heavy metal oxide (15 per cent by weight of ferric oxide) was added, the bomb was closed and the mixture subjected to further oxidation under substantially the same conditions as in the first stage.

After this treatment, the resinous material was drawn off hot, mixed with an equal weight of wood flour and about two per cent of hexamethylenetetramine (calculated on total weight of resin and filler) was added. The resulting mass was worked on hot rolls at about 175°C., and the final resin pulverized to yield a powder capable of hot molding. Morrell[70] suggests an analogous treatment using ozonized air as the oxidizing agent in place of the air-oxygen mixture.

The large variety of useful materials obtained by oxidation treatment is indicated by a report of Velikovskaya[71] on the utilization of by-products of the petroleum industry. From the acid sludge produced in spindle oil refining, he reports, a satisfactory axle grease can be made. The acid sludge is heated to 300°C. and blown with air till it solidifies. The product is then heated to 170°C. and diluted with mineral oil to the desired viscosity and finally treated with 1 per cent of 35° Baumé sodium hydroxide. A shoemaker's wax can be prepared from heavy oil bottoms stripped of fractions boiling below 300°C. and similarly blown with air until solidification sets in. This product is then mixed with 20 per cent of heavy distillate alkali sludge or with oil separated from acid sludge after it has been blown with air. A binder material from the manufacture of briquets can also be prepared from acid sludge.

Insecticides. Investigations by Francis[72] on the efficiency of insecticides indicated that although the exposed feeders, such as caterpillars, hoppers, beetles and bugs, are best controlled by applications of poisons on the feeding materials and contact insecticides, the concealed feeders such as leaf miners, borer and ants are most readily attacked by gases and a number of petroleum preparations. The sucking insects are most difficult to control, since the feeding materials cannot be poisoned. For this type of pest, substances which affect respiration or have a caustic effect on the skin are used; insect powders, tobacco, and petroleum distillates. Household moths are eradicated by suffocants; carbon disulphide, hydrogen cyanide or volatile petroleum products. It was shown in tests carried out at the New Jersey Agricultural Experiment Station that insects normally have a coating which is highly resistant to the penetration of water. Petroleum distillates overcome this natural protection. The lighter oils have, *per se*, a caustic action on the softer parts of the insect's body. According to Petrov,[73] the paraffin base oils are best suited to the preparation of insecticides, and the naphthenic oils are distinctly inferior. A number of Russian oils were tested as insecticide preparations, and it was found that this general comparison holds. Aromatic content is particularly undesirable in insecticide oils due to the burning action it evidences when applied to plant foliage.[74] Hyman[75] has prepared an insecticide by oxidation of a vapor-phase cracked petroleum distillate boiling in the kerosene to gas-oil range. The cracked product is treated with molecular oxygen in the presence of a siccative soap or other siccative compound of cobalt, lead or manganese. When precipitation ceases, the solid is separated out and the filtrate recovered. It has also been suggested that the sodium salts of the saturated aliphatic acids of medium molecular weight (4 to 15 carbon atoms) make effective insecticides. These can be prepared, Burwell[76] states, by the oxidation of petroleum fractions. The hydrocarbon is oxidized (with oxygen or air) under pressure of 250 pounds per square inch in the presence of manganese oleate at a temperature of 155°C. The product is said to be useful as a constituent of insecticidal sprays.

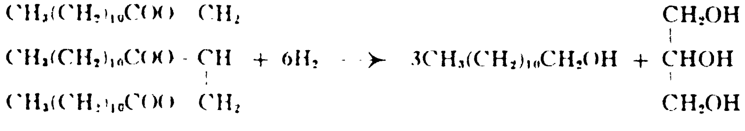
Derivatives of the higher alcohols have been tested as contact insecticides, according to Bousquet, Salzberg and Dietz,[77] and the results obtained have been encouraging. These higher alcohols can be obtained by the oxidation of the higher petroleum derivatives, though in the present investigation they were derived from cocoanut oil and transformed to the rhodanates for the insecticide tests. The following series of reactions was employed, starting with trilaurin:



$$\begin{array}{l} CH_3(CH_2)_{10}COO-CH_2 \\ \qquad\qquad\qquad\quad | \\ CH_3(CH_2)_{10}COO-CH \\ \qquad\qquad\qquad\quad | \\ CH_3(CH_2)_{10}COO-CH_2 \end{array} + 6H_2 \longrightarrow 3CH_3(CH_2)_{10}CH_2OH + \begin{array}{l} CH_2OH \\ | \\ CHOH \\ | \\ CH_2OH \end{array}$$

$$CH_3(CH_2)_{10}CH_2OH + HCl \longrightarrow CH_3(CH_2)_{10}CH_2Cl + H_2O$$
$$CH_3(CH_2)_{10}CH_2Cl + NaSCN \longrightarrow CH_3(CH_2)_{10}CH_2SCN + NaCl$$

By starting with cocoanut oil, it is possible in this way to obtain the rhodanates of all the even-numbered carbon atom alcohols from six to eighteen carbon atoms. These include hexyl, octyl, decyl, lauryl, myristyl, cetyl and stearyl rhodanates. Hexyl rhodanate is an oily liquid boiling at 85°C. whereas stearyl rhodanate is a waxy solid boiling at 195°C. under 2 mm. pressure. The lower rhodanates have powerful and unpleasant odors whereas the longer chain compounds are much less objectionable. Lauryl rhodanate has a mild and fatty odor.

A series of tests made against several varieties of aphids, red spiders and thrips showed that the 12 carbon (lauryl) rhodanate was uniformly the most effective. In several instances it was found that the lowest rhodanates tested (methyl, ethyl and butyl) were positively advantageous to the insects, since potassium oleate, the wetting agent employed in conjunction with the insecticides, was more toxic alone than the combination of oleate and butyl rhodanate. There was a sharp increase in toxicity with hexyl rhodanate, a further distinct increase for octyl rhodanate, and a lesser gain, and in some cases (as against the green chrysanthemum aphid) little or no gain in going to the decyl rhodanate. The curve of toxicity flattens between the decyl and lauryl rhodanates, thence declining rapidly for myristyl, cetyl and the higher compounds. (See Figs. 252 and 253.) It was found in testing various concentrations that lauryl rhodanate in 0.067 per cent concentration caused practically a 100 per cent kill of green chrysanthemum aphids. Since this 12-carbon rhodanate showed greatest promise, it was tested in some detail as to plant toxicity and is reported to allow a sufficient margin of safety for effective use as a practicable insecticide.

James[78] suggests that the mixed oxidation products of a gas oil may be treated with sulphuric acid or oleum, producing sulphates and sulphonates of the unsaturated compounds present. By neutralization of the acid mixture, hydrolysis of the sulphates occurs, yielding higher alcohols, which, he states, may be combined with a toxic agent to produce an insecticide. If the neutralization is effected by the addition of sodium sulphide to the acid liquors, the sulphur content of the product is reported to be about 2.5 per cent. The sulphur has in part, he finds, reacted to form thio ethers, which act as a toxic agent to the insects, without injuriously affecting foliage. Chlorine or nitrogen compounds may be introduced into the organic molecule instead of sulphur.

Emulsifying Agents. The acids and esters of oxidized petroleum fractions have considerable emulsifying powers, and their cheapness makes them desirable in many processes. Eigeles[79] has reported tests made on the flotation of Kalanguev fluorite ore, using oxidized paraffin and the mixed carboxylic acids separated from it. In this service it was found that the best solvent for the oxidized paraffin was benzene, although the carboxylic acids gave satisfactory results with kerosene. Up to 16 per cent of the oxidized paraffin solution can be used, and solutions containing 30 per cent of the carboxylic acids were tested. It was reported that these solutions were less sensitive to variations of the pH values than were oleic acid flotation solutions. However, an optimum result was obtained at pH of 11. The best temperatures for the operation varied somewhat, that for the oxidized paraffin being 23° to 24°C., although the carboxylic acids gave good results at 12°C. The addition of pine oil improves the flotation by petroleum oxidation products, although the regular procedure used in the oleic acid flotation gives equally good results (*e.g.*, 81.4 per cent of the calcium fluoride present in the ore

before treatment was extracted into the flotation concentrate. The concentrate analyzed 96 per cent fluorite.) when the oxidized paraffin is simply substituted.

Some of the oxidized petroleum compounds also have the power to break emulsions of the water-in-oil type. Thus Burwell[80] oxidized petroleum oil hydrocarbon at 155°C. under a pressure of 350 pounds per square inch in the presence of manganese oleate. The ketonic fraction of the product or the mixed acids or their sulphonation products may be employed in breaking petroleum emulsions. Similarly, sulphonated oxidized products of higher petroleum hydrocarbons can be used as wetting and dispersing agents in making oil-in-water emulsions.[81]

SPECIAL METHODS OF COMBUSTION

A special case of partial oxidation of hydrocarbon oils has been suggested by Janssen,[82] using a slurry of oil and metal ore. Oil and finely divided ore are thoroughly mixed, and air is blown through the mixture in the presence of a catalyst to produce fatty acids. Alkali is added to the mixture so produced to form soaps. The fuel slurry is then atomized and burned with such a quantity of air that incomplete combustion takes place and the metal ore is reduced.

In an effort to secure greater fuel efficiency, submerged combustion has been studied from time to time. Thus, according to Kobe,[83] one type of commercial submerged combustion burner, consuming hydrocarbon gas and air, will utilize the latent heat of volatilization of the water produced by the combustion since the products of combustion are cooled to the temperature of the liquid being heated. The burners are capable of converting over 90 per cent of the available energy of the fuel-air mixture into useful heat, this investigator indicated. Kobe, Conrad and Jackson[84] reported experiments with submerged combustion burners and found that three essential considerations in the construction of such a mechanism were: (a) a mixing chamber which would produce a homogeneous air-gas mixture, (b) a velocity tube through which the air-gas mixture flows at a rate greater than the rate of flame propagation in the mixture, and (c) a combustion chamber containing a refractory surface which becomes incandescent and acts as an ignition point for the fuel mixture. With an experimental burner constructed according to these observations, the thermal efficiency in evaporation of water (percentage of heat input recovered in products) was 95.2 per cent, while 83.6 per cent of the heat input was used in evaporating the water. The investigators tried submerged combustion evaporation in the concentration of sulphite waste liquors. The most serious problems in the evaporation of these liquors are the viscosity of the fluids, the serious scale-forming tendencies, the corrosive nature of the unneutralized liquid, foaming, and the escape of volatile substances causing trouble in condensing. Submerged combustion makes possible the use of poor heat-conducting materials such as ceramic ware which resist corrosion, while scale does not interfere with heat transfer from a gas bubble. The continuous release of gases tended to agitate the material satisfactorily, and good concentration results were reported. Since these experiments, Kobe, Hague and Carlson[85] have studied the dehydration of sodium sulphate decahydrate by submerged combustion. The dehydration of this salt is difficult because of the peculiar solubility curve of the compound. At 32.4°C. this salt forms solid sodium sulphate and a saturated solution. Evaporation must be conducted below this temperature, then, if scale deposition is to be avoided, or the evaporation process must start with a saturated solution rather than the decahydrate itself. With tube evaporators, there must be considerable surface at a temperature higher than that of the liquid, with consequent deposition of the anhydrous salt on these surfaces and lowered efficiency resulting from poor heat transmission. On the other hand, submerged combustion is said to be highly advantageous in that no large metal surfaces are exposed at temperatures higher than that of the liquid. Some scale does form on the burner, but the unit need not be shut down; the burner is withdrawn, another burner being inserted. When submerged combustion is employed, solid decahydrate may be used as the feed material, reducing the required evaporation. Further, the inverted solubility curve

Stewart[87] has pointed out a further advantage of submerged combustion as a source of heat; it makes possible an extremely compact boiler-burner unit. For instance, he has made an apparatus for domestic heating consisting of an angled pipe enclosing a tubular burner. The annular space between the inner burner tube and the external pipe contains the water of the boiler system. (See Fig. 254.) Air-fuel mixture is supplied to the burner by a small compressor. If used in conjunction with a domestic hot-water heating system, the burner is preferably placed at the top of the house, in order that the water-head on the burner may be minimized. Circulation in this system is not dependent on convection currents, since the combustion gases forced from the burner serve to maintain a rapid circulation through the burner-boiler unit and hence through the entire system. The intimate contact of combustion products and water makes heat transfer highly efficient (over 90 per cent), it is said. The small size of the apparatus required makes practicable the use of corrosion-resistant materials without undue increase in cost. Further, because the gases are fed by means of a small blower, and the combustion products leave the system at a temperature below the boiling point of water, a chimney or flue is unnecessary, since high temperature gases need not be handled, and draft is otherwise supplied. The exhaust flue may be a 1-inch malleable iron pipe. This type of apparatus is not limited to direct heating, however, since the burner-boiler unit is sufficiently compact to be immersed directly in a fluid which is to be heated without contact with the combustion gases.

Chapter 46

Sulphonation of Petroleum Hydrocarbons. Sulphonic Acids, Detergents and Other Products

In view of the large-scale application of acid refining of petroleum distillates, the action of sulphuric acid and of oleum on various fractions is of importance. In addition to its action as a solvent and precipitating or coagulating agent, the acid effects sulphonation, polymerization and sulphation of petroleum hydrocarbons. In many instances, some oxidation also occurs simultaneously. A consideration of the solvent or precipitating action of the acid involves a discussion of petroleum refining which is beyond the scope of this text. The sulphation and polymerization which take place with olefins has been described previously.[1] In this chapter attention is directed particularly to sulphonation, especially of paraffin hydrocarbons.

The early use of sulphuric acid in petroleum refining[2] soon led to the serious problem of disposal of the acid sludge, a highly corrosive substance,[3] which, however, contained considerable amounts of valuable constituents. The sludge was diluted with water, causing a separation into two layers. The aqueous layer was reconcentrated and the sulphuric acid re-used; the insoluble oily residue was burned as a fuel.[4]

As uses have developed for the substances present in the acid sludge, many workers have investigated methods of separation applicable to such complex mixtures. The characteristics of sludges depend on the properties of the original crude, the fraction treated, and the method of treatment. The latter varies in severity from the mild processes employed in refining light gasoline distillates, through the more severe treatment of lubricating oils to the rigorous operations necessary in the manufacture of white oils and petrolatum where the most concentrated acid, and frequently fuming oleum, is used.[5]

PROPERTIES OF SULPHONIC ACIDS

Since accurate knowledge of the mechanism of sulphonation is limited to the reaction of hydrocarbons of relatively low molecular weight, only inferences can be drawn regarding the reactions of the larger molecules present in petroleums. It appears that the saturated hydrocarbons in the higher distillates of many oils are much more reactive toward chemical reagents, sulphuric acid included, than are the simpler saturated compounds, while the almost unknown class of polynuclear cycloparaffins may embrace more highly reactive constituents than has been suspected.

---

[1] See Chapters 13, 14 and 15 for sulphation, and Chapter 26 for polymerization.

[2] For more details of earlier work see Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., Inc., New York, **1934**.

[3] For a discussion of this, see K. P. Likhushin, *Neft. Khoz.*, **1934**, No. 9, 87; *Chem. Abs.*, 1935, **29**, 6032; *Brit. Chem. Abs.* **B**, 1936, 627.

[4] A modification of this process, using water and a substantial proportion of a spacing agent such as a sulphate or sulphonate has been described by J. C. Morrell (U. S. P. 1.930.249, Oct. 10, 1933, to Universal Oil Products Co.; *Chem. Abs.* 1934, **28**, 312). Settling separates the sludge into an oily layer and an aqueous layer; fresh acid is added to the aqueous layer.

[5] See for example A. Lazar, U. S. P. 1,964,953, July 3, 1934, to Associated Oil Co.; *Brit. Chem. Abs.* **B**, 1935, 1023; *Chem. Abs.*, 1934, **28**, 5181. Also K. T. Steik, *Am. Dyestuff Reptr.*, 1934, **24**, 480; *Chem. Abs.*, 1935, **29**, 6766; *Brit. Chem. Abs.* **B**, 1935, 989, and B. K. Tarasov, *Neft. Khoz.*, **1929**, No. 16, 236; *Chem. Abs.*, 1929, **23**, 4812.

As the chemical and physical properties of acid sludges are dependent on a number of factors, investigations of these complex mixtures have been difficult and many procedures have been advocated for separation of the sulphonic acids therefrom. The latter in turn may be subdivided in two ways, according to their solubility, or that of their calcium salts in various solvents. Thus the so-called "mahogany acids" are oil-soluble and the "green acids" are water-soluble. The calcium salts resulting from neutralization of acid sludge by calcium carbonate (or hydroxide) can be separated into three classes, the α-, β- and γ-sulphonates as follows:[6]

α-Sulphonates: Found mainly in the acid sludge, but also in the oil layer. The calcium salts are insoluble in water and ether.

β-Sulphonates: Found largely in the oil phase, but also occur in the sludge when oleum is used. Calcium salts are insoluble in water, but soluble in ether.

γ-Sulphonates: Found almost entirely in the acid sludge. The calcium salts are soluble in water, insoluble in ether.

Taking advantage of this means of separation, von Pilat and Szankowski[7] extracted γ-calcium sulphonates obtained by sulphonation of a transformer oil and regenerated the hydrocarbons from them. The oils so secured gave evidence that these γ-acids were derived from a homologous series of aromatic hydrocarbons (without long side-chains), the heavier fractions showing indications of condensed ring-systems. The ratio of carbon to hydrogen atoms in the molecule (about one to one) holds even with increasing molecular weight. The oils are characterized by high refractive indices, a very steep temperature-viscosity curve and a density about unity.

Sereda[8] has reported a specific test for the β-sulphonic acids that is said to be unaffected by the presence of naphthenic or polysulphonic acids. Ferric salts react with the β-acids to form a compound intensely blue in ether solution. The color is not given by either the α- or the γ-acids, and when conducted with a *p*H value between 2 and 9, the response is discernible in concentrations as low as one part in 5000.

A separation[9] of mixed naphthenic and sulphonic acids and petroleum oils can be brought about by treating a dilute aqueous solution of the neutralized salts with ether to remove free oils, followed by a cold brine solution. The sulphonic salts react with the brine to form water-soluble sodium salts, while the naphthenic acids do not. The latter may then be extracted with a light petroleum. It is reported that a determination made in this way is accurate to 0.2 to 1 per cent (determined on total original mixture).

Investigating α- and γ-sulphonic acids, Neyman and von Pilat[10] determined the surface-tension effects of the sodium salts and showed these substances to be much more effective in decreasing surface tension of water than was sodium oleate.

[9] S. von Pilat and J. Sereda, *Fettchem. Umschau*, 1934, **41**, 171, 200, 237; *Brit. Chem. Abs.* **B**, 1935, 132; *Chem. Abs.*, 1935, **29**, 2702.

[10] E. N. Neyman and S. von Pilat, *Ind. Eng. Chem.*, 1934, **26**, 395; *Chem. Abs.*, 1934, **28**, 4577; *Brit. Chem. Abs.* B, 1934, 486. According to these investigators α- and γ-sulphonic acids constitute about 25 to 40 per cent of the bulk of the acid sludge obtained from treatment of lubricating oils with concentrated sulphuric acid. See *Ind. Eng. Chem.*, 1934, **26**, 651.

The surface tensions of 0.1 per cent solutions of the sodium salts of oleic, α- and γ-acids were 65, 51 and 54 dynes per square centimeter, respectively. Dialysis using a triple collodion membrane permitted complete separation of the γ-sulphonate from the larger molecules of the α-salt, and by analysis it was determined that the γ-salt contains about 31 atoms and the α-salt twice that number. Solutions of 0.01 per cent strength showed only a feeble Tyndall effect under the ultramicroscope, and no Brownian motion.

Vivian and Reid[11] prepared some of the lower alkyl sulphonic[12] acids by oxidation of corresponding mercaptans and dehydration, at one millimeter pressure, of the resulting concentrated aqueous solutions. The acids appeared unstable and soon darkened even when stored *in vacuo*. Investigations of the melting points of the alkyl sulphonic acids containing from 1 to 6 carbon atoms showed an alternation of melting points closely paralleling those of the corresponding carboxylic acids. (See Fig. 255.) Reed and Tartar[13] investigated the aqueous solutions of the calcium, magnesium and sodium salts (prepared by the Strecker reaction[14]) of the higher alkylsulphonic acids through octyl, decyl, lauryl, myristyl, cetyl and *n*-octadecyl. Investigations of surface tension showed a considerable time-function, and the capillary rise method was recommended for studying this property. Considerable time (more than a month) was required before these capillary surface tension values reached equilibrium. Similar time effects were found in measuring the interfacial tension of the aqueous solution against benzene, though the factor

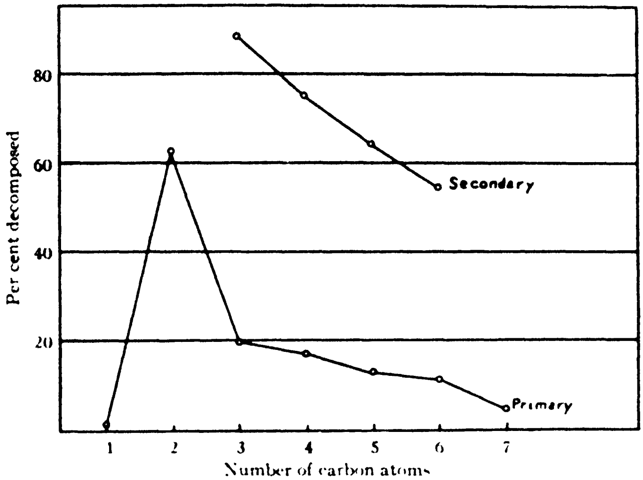
[14] For a general discussion of this reaction see Chapter 34. In this case the reaction used was:

$$RI + (NH_4)_2SO_3 \longrightarrow RSO_3NH_4 + NH_4I$$

in this case was measured in weeks rather than months. Conductivity experiments demonstrated that the sodium alkyl sulphonates are similar in this respect to potassium fatty acid soaps.

Although the sulphonic acids react as strong acids, Dominikiewicz[15] reports that amphoteric elements such as aluminum form two types of salts, a true aluminum sulphonate and a second type of salt in which the aluminum atom is a part of the aluminosulphonic acid ion.[16]

The stability of aliphatic sulphonic acids, probably because of the carbon-sulphur linkage, is shown by the fact that they are not hydrolyzed by aqueous alkali except when heated to temperatures of 315 to 375°C.[17] Under such conditions three reactions are possible, viz.:



Courtesy Journal of American Chemical Society

FIG. 256.—Decomposition of Aliphatic Sulphonic Acids with 3.70 N Sodium Hydroxide. 3 Hours at 345°C. (F. C. Wagner and E. E. Reid)

$$RCH_2CH_2SO_3Na + NaOH \longrightarrow RCH{=}CH_2 + Na_2SO_3 + H_2O$$
$$RCH_2CH_2SO_3Na + NaOH \longrightarrow RCH_2CH_3 + Na_2SO_4$$
$$RCH_2CH_2SO_3Na + NaOH \longrightarrow RCH_2CH_2OH + Na_2SO_3$$

Although no alcohols have been isolated as a result of such reactions, nevertheless in some instances it was reported that the hydrolytic products contained alkali salts of carboxylic acids having the same number of carbon atoms as the initial sulphonic acid. For example, *n*-butyl and *n*-amyl sulphonic acids yielded butyric and valeric acids, respectively. This appeared to indicate that the third reaction (given above) was the main one, followed by interaction of the liberated alcohol and alkali at high temperatures.

$$RCH_2CH_2OH + NaOH \longrightarrow RCH_2COONa + 2H_2$$

Comparisons of percentage decompositions of various aliphatic sulphonic acids, with 3.70 N sodium hydroxide for 3 hours at 345°C., indicated methyl sulphonic to be the most, and ethyl sulphonic the least, stable. The stability of acids having higher molecular weights then increased with the number of carbon atoms per molecule. This is shown graphically in Fig. 256. In general, sulphonic acids derived from secondary hydrocarbons were less stable than those from primary hydrocarbons. The effect of temperature (when the same concentration of alkali and the same heating time mentioned above were employed) is illustrated in Fig. 257. It will be noted that for the same percentage decomposition much higher temperatures are required in the case of primary sulphonic acids than for the corresponding secondary compounds.

FIG. 257.—Effect of Temperature on Decomposition of Aliphatic Sulphonic Acids with 3.70 N Sodium Hydroxide. (F. C. Wagner and E. E. Reid)

However, despite the strong resistance of sulphonic acids to hydrolysis (even in the presence of caustic alkali), Sereda, Macura and Udrycki[18] report that the interaction of these acids and organic bases such as aniline results in splitting of the carbon-sulphur bond comparatively readily. Up to about 160°C., the reaction between aniline and sulphonic acids yields the expected anilides. When the two reactants are heated above this temperature, the products are chiefly sulphanilic acid and a hydrocarbon.

$$RSO_3H + C_6H_5NH_2 \longrightarrow H_2NC_6H_4SO_3H + RH$$

The reaction followed the same course with *o*-toluidine, yielding 3,4-methylaminobenzenesulphonic acid. However, *p*-toluidine did not effect the removal of the sulphonic group even on prolonged boiling, reaction beginning at 230°C. under pressure. When dry *p*-toluidine was heated with absolutely anhydrous sulphonic acids at this temperature, 5,2-methylaminobenzenesulphonic acid was formed. From these reactions it was believed that when the position para to the amino group is occupied, the sulphonic group is directed to the ortho position.

PRODUCTION OF SULPHONIC ACIDS

Parkhomenko[19] reports that for best results both the oil and the oleum employed should be of uniform quality. He recommends that 18 to 20 per cent of oleum (23 to 25 per cent free sulphur trioxide) be used in four treatments of two and a half hours, the temperature being maintained at 75 to 80°C. The use of air for agitating the reactants is not advisable. In separating the acids produced, a thorough settling is necessary, and he recommends that two settlings in separate vessels be made, at a temperature of 45 to 50°C. By these methods, he found a sulphonic acid-oil ratio of 2:1 in the first two extractions and about 4:3 in the last two. Voznesenskii[20] treated a distillate (initial boiling point 220°C., 85 per cent over below 240°C.) with 20 per cent oleum four successive times, and a yield of nearly 40 per cent of sulphonic acids was obtained. These acids were found to be effective fat-hydrolyzing agents, although the sulphonic acids obtained from liquid petrolatum were 120 per cent better in this respect. Khisin and Sungalovskaya[21] report sulphonating a heavy fraction (boiling between 275 and 350°C.) of a Gdov shale-oil tar to make effective soaps. The oil was treated with 150 per cent of its volume of sulphuric acid for one hour at 60°C. A yield of 60 per cent of sulphonic acids was reported, and the sodium or ammonium salts of these acids were found to be serviceable soaps.

Sulphur trioxide in gaseous form may be employed as the sulphonating agent, and according to Sarkisov, Gotovtzev and Razderishin,[22] this method is advantageous in that it makes possible a higher concentration of sulphonic acids in the crude products. By using gaseous sulphur trioxide and dry air blown through oil at a temperature of 110 to 120°C. the sulphonic acid concentration was increased 15 per cent, while the free sulphuric acid concentration in the solution was held to a minimum. Some investigations by Likhushin, Dei-Karkhanova and Shaknovich,[23] in which various petroleum distillates were treated with sulphur trioxide, led them to the conclusion that petroleum sulphonic acids were not formed from naphthenic acids, but from naphthenic hydrocarbons that had suffered dehydrogenation. Shneider and Kheifetz[24] reported, however, that in treating a gas oil with sulphur trioxide, they were able to increase the yield of sulphonic acids by 50 per cent when 4 per cent of naphthenic acids were added. This observation was confirmed by Likhushin, Dei-Karkhanova and Mirzakulieva.[25] The latter investigators treated distillates (at 60 to 63°C.) with 4 portions of sulphur trioxide (a total of 12 per cent being used). Very high yields of acids were obtained, and it was concluded that there was either a catalytic action caused by the naphthenic acids present, or that the naphthenic acids had a dissolving action on the sulphonic acids in the distillates.

Such powerful sulphonating agents as sulphur trioxide are seldom used in usual refining operations, but the trioxide may be modified to yield a maximum proportion of sulphonic acids with a minimum of oxidation, using sulphuric acid as the refining agent. The best conditions for such results are 10 per cent (by weight) of 96 per cent sulphuric acid at −10°C. Less concentrated acid (90 per cent) can be used at a higher temperature (+15°C.) if a larger proportion (20 per cent) is employed.[26]

Osborn and Craig[27] find that the fraction of petroleum hydrocarbons extracted by liquid sulphur dioxide is practically wholly composed of sulphonatable constituents. Such an extract is treated with an approximately equal proportion of 90 to 103 per cent sulphuric acid, and after the reaction, water is added to bring about stratification. The product is a concentrated solution of water-soluble sulphonic acids. This procedure is said to be advantageous in that it requires comparatively small bulks of corrosive acid and correspondingly smaller corrosion-resistant apparatus.

EXTRACTION AND PURIFICATION OF THE PETROLEUM SULPHONATES

In recovering the sulphonic acids derived from petroleum oils, two general methods are employed: the selective solvent action of the lower monobasic alcohols and precipitation of the petroleum sulphonate salts by salting out.[28] Thus, Ramayya[29] dissolves the organic acid constituents in acid sludge by treatment with 25 to 75 per cent aqueous ethyl alcohol. Reddish and Myers[30] employ an analogous process, and recommend that the proportion of sludge to alcohol be such that there is less than 20 per cent by weight of sulphonic acids in the final alcoholic solution. Buc[31] suggests that the extraction be made with a 50 per cent aqueous solution of isopropyl or higher water-soluble alcohol. The sulphonates taken up by the alcoholic solution are purified by precipitating the ionizable salts in an aqueous layer formed by a dehydrating agent such as sodium carbonate monohydrate. The dehydrating agent is added, separation takes place, and the two solutions are separately distilled to recover, from the alcoholic layer, the sulphonates, and from the aqueous layer, the sodium carbonate for further use as dehydrating agent. The method is said to be advantageous in that it permits purification with but a single distillation and extraction process.

Salting-out of sulphonates is advocated in some instances as a method of securing only the more desirable compounds. Thus, acid sludge is neutralized with sodium hydroxide and the aqueous solution treated with 2 to 15 per cent of sodium chloride to precipitate the sodium sulphonates.[32] Fussteig[33] reports, on the other hand, that the resulting products are often contaminated with portions of neutral oil. The latter may be removed, however, by extracting an aqueous alkaline solution of the sulphonates with acetone or ether. Vesterdal and Carlson[34] find that refining of green-acid salts may be effected by fractional precipitation from an aqueous solution of the salts by means of water-soluble organic liquids (such as acetone or alcohol) and salt. As the temperature of the solution is lowered, the sulphonate fractions separate out. If the acid sludge is neutralized with an aqueous lime slurry instead of sodium hydroxide, the insoluble alkaline-earth metal salts of the sulphonic acids are formed. Pilat and Sereda[35] mix the mass of precipitated sulphonates, asphaltenes, tars and resinous compounds from such a treatment with alkali carbonates, thereby converting the sulphonates into water-soluble compounds which are afterwards removed by extraction.

[28] So greatly do acid sludges vary in nature that no generalization is entirely safe. It is best to say only that a certain sludge, treated in the described manner, will yield products suitable for applications suggested. E. Holzman and S. Suknarowski (*Ind. Eng. Chem., Anal. Ed.*, 1935, **7**, 378; *Chem. Abs.*, 1936, **30**, 275) have developed a system of analysis that can be applied to these sludges that may be of assistance in determining what treatment would be best adapted to a particular sludge.

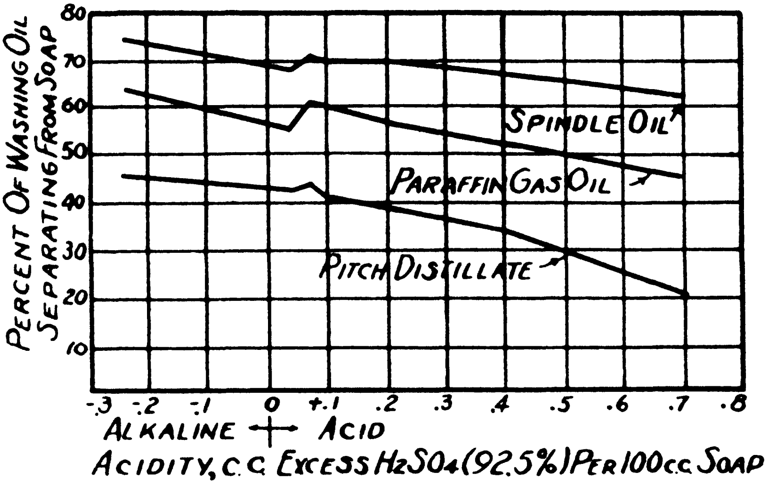

FIG. 258.—Effect of Soap Acidity on Separation of Light Hydrocarbon Oil from Green-Acid Soap. (R. E. Beard and E. N. Roberts)

Ramayya[36] refined crude oil-soluble mahogany sulphonates by dissolving them in an aqueous solution of a lower monohydric alcohol (such as isopropanol). The solution is separated from the sludge, and agitated with a light petroleum distillate. On settling, the solvent layer is separately collected and evaporated to recover the refined salts. Extraction with propane, at 50 to 95°C. and under sufficient pressure to maintain the hydrocarbon in the liquid state, has been suggested.[36a] Beard and Roberts[37] remove these mahogany acids from acid-treated oils by taking advantage of the differential solubility of their salts in a green-acid soap solution (an aqueous solution of neutralized green acids). This relationship is shown by the graphs in Figs. 258 and 259. Thus, an acid-treated oil is neutralized with caustic soda and extracted with about 12½ (volume) per cent of a 10 per cent aqueous solution of green-acid soap. Practically all the mahogany-acid salts are taken up in this soap, separated from the refined, finished oil. The green-acid solution is acidified with 0.5 to 1.0 cc. of 92.5 per cent sulphuric acid per 1000 cc. of soap solution. The specified amount of acid is chosen since, at this acidity, the mahogany acids are more soluble in oil than in green-acid soap solution, and can be extracted by a light petroleum distillate. Further, the degree of acidity assures a clean-breaking emulsion of the light distillate and the soap. The light distillate extract is removed and evaporated to recover the mahogany components, and by neutralizing the green-acid soap solution it may be reused as an extracting medium. A flow diagram of the procedure is shown in Fig. 260.

Many other methods for refining petroleum sulphonates have been proposed. For example, Limburg[38] suggests treating an aqueous solution of the sulphonates with an organic base such as aniline, which forms insoluble compounds with the sulphonates. Instead of forming a salt with an ammonia derivative, Bird and Rosen[39] purify the water-soluble salts by a double extraction process, involving the usual crude separation of the sulphonates in an alcohol, and a subsequent refining in liquid ammonia. These investigators report that liquid ammonia acts as a highly selective solvent for the lower water-soluble sulphonic acids. The ammonia solution of the sodium sulphonates is filtered, and the filtrate evaporated, to obtain the purified sulphonates. The powder so obtained consists of the purified, relatively low molecular weight, fraction of the sodium sulphonates. It is lighter in color than the crude mixture of sulphonates used as starting material, and is re-

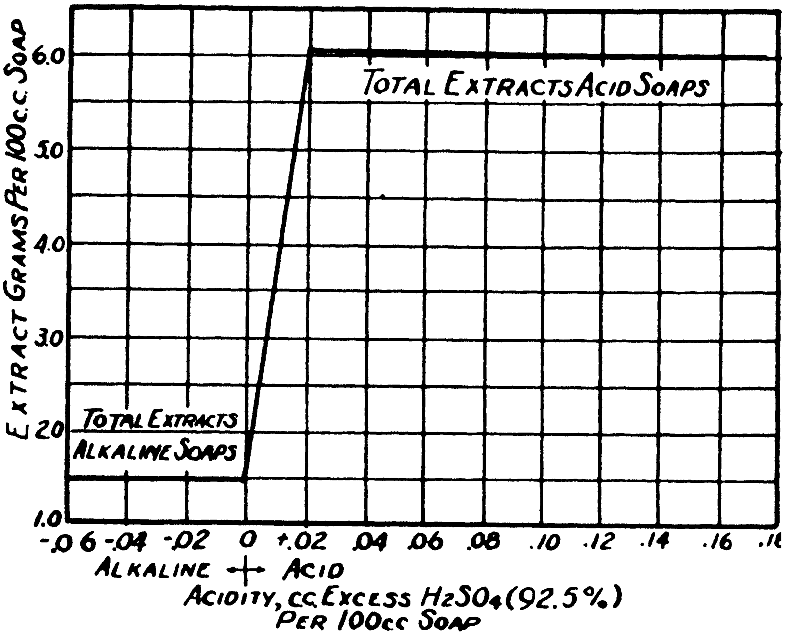

FIG. 259.—Influence of Soap Acidity on Efficiency of Light-Oil Extraction of Green-Acid Soaps. (R. E. Beard and E. N. Roberts)

ported to be more effective as a wetting agent. Another proposed method of separation involves osmosis of the dissolved sulphonates against water.[40]

It is reported that naphthenic acids, obtained in alkali treatment of burning oils, may be employed in the extraction of petroleum sulphonic acids.[40a] Dennemark[41] points out that the latter compounds, particularly those derived from naphthenes, may be freed of sulphuric acid by dialysis.

INDUSTRIAL APPLICATIONS OF PETROLEUM SULPHONIC ACIDS AS DETERGENTS

The petroleum sulphonic acids are mildly detergent, and their stability to hard water, acid and alkaline solutions makes them useful in some applications. Liberthson[41a] has prepared water-soluble petroleum sulphonates in flakes by extracting the green acids, converting these to water-soluble salts, and taking up the salts in a solvent. The resulting solution is applied in a thin film to a smooth heated metal surface, and the subsequent evaporation causes a deposition of solid laminar fragments which can readily be dislodged and collected. Other investigators recommend preparing the sulphonates in a concentrated solution. Hintzmann[42] finds that the sodium sulphonates are more soluble in aqueous solutions of urea or thiourea than in pure water and suggests this as a means of making a concentrated solution. As an example, 35 parts of sodium sulphonate with 17 parts of urea were dissolved in 45 parts of warm water. Some of the alkali metal sulphonates tend to form turbid solutions in water, which Diependruck[43] reports can be clarified by the addition of approximately 15 per cent of a highly refined spindle or cylinder oil. The detergent and cleaning properties can be enhanced, it has been reported, by mixing the acid sludge sulphonates with an alkali metal alkyl hydrogen sulphate

of more than 10 carbon atoms per molecule.[44] Incorporation of the sulphonates is reported to materially increase the solubility of the sulphate derivatives in water.[44a]

PETROLEUM SULPHONIC ACIDS IN EMULSIONS

Petroleum sulphonics may be employed in making stable hydrocarbon emulsions, and, conversely, may be used as constituents of emulsion-breaking mixtures. Gelbke[45] prepares an emulsifying agent useful in textile and leather work from the crude sulphonic acids. The acids are first dehydrated by treatment with superheated steam, followed by vacuum distillation. They are then dissolved in 94 to 98 per cent ethyl or methyl alcohol and the solution allowed to stand at 0°C. until clear. Distillation of the alcohol yields a product reputed to have high emulsifying power.

Limburg[46] recommends a specially treated spindle oil fraction as a source of petroleum sulphonic acids yielding calcium salts soluble in water and in aqueous solutions of calcium chloride. The spindle oil distillate is first treated with not less than 30 per cent of strong sulphuric acid, and after separation from this treatment the oil is subjected to the action of a second quantity of sulphuric acid. The acid sludge from the second treatment is neutralized, and the resulting salts furnish emulsifying agents capable of stabilizing aqueous emulsions of mineral and vegetable oils and asphalts. Liberthson[47] stabilizes an asphalt emulsion with mixed green-acid salts. The acids are freed of non-acid oily materials by solution in an alcohol of low molecular weight, such as ethanol, and after recovery from this solution are converted to the water-soluble sodium or potassium salts.

Ramayya[48] suggests the use of a mixture of green and mahogany acids. The crude acids are freed of uncombined sulphuric acid (by extraction with isopropyl alcohol) and reacted with alkali or ammonium bases to form salts. Thirty per cent of mahogany acid salts similarly prepared are admixed. The water content should be less than 30 per cent, and under these circumstances the products are readily soluble in hydrocarbons and tend to form stable emulsions.

The emulsifying properties of the sulphonic acids can be enhanced by the addition of various other substances, such as a mixture of mahogany acids, a hydroxyamine of a fatty acid (e.g., triethanolamine oleate) and a homogenizer such as a polyhydric alcohol.[49] Chamberlain[49a] recommends that petroleum sulphonic acids be employed in conjunction with sulphonated castor oil. Sereda[50] suggests that adding mineral hydrocarbon oil, a protective colloid, and a small proportion of a finely divided, water-insoluble, substance such as kaolin to the sulphonic acids or their salts improves their emulsive powers. By combining a soluble deflocculent agent with sulphonic acids as emulsive agents, DeGroote[51] has produced a mixture stated to lessen clogging of pipe lines and oil wells containing flowing oil. The solid matter is kept in suspension in a non-flocculent condition by these agents, preventing accumulations of solid matter that tend to restrict the flow of the liquid.

The petroleum sulphonic acids are effective also in breaking emulsions of the water-in-oil type. Bukh, Pivovarova and Mirzoeva[52] report dehydrating a heavy Baku crude with 1 per cent of "black Kontakt" (petroleum sulphonates derived from an acid-treated kerosene fraction). The emulsion was broken at a temperature of 90 to 95°C., or even lower. It is suggested that this action is the result of the formation of oil-soluble calcium sulphonates by an interaction between the sulphonic acids and calcium naphthenates, and that calcium sulphonates thus formed bring about the separation. Bukh and Mirzoeva[53] add that they prefer the black Kontakt because of its cheapness, its consistency and the ease with which it can be handled. The actual treatment takes only 20 to 30 minutes; the entire operation approximately 1 hour. Fischer and Reddish[54] have proposed that ethyl alcohol be added to the petroleum sulphonates used in breaking emulsions of the water-in-oil type. They find that the alcohol acts as a viscosity reducing agent and accelerates coalescence. DeGroote and Keiser[55] use equal quantities of green and mahogany acids and add to them a strongly oxidized castor oil and about 10 per cent of kerosene for this purpose. An earlier suggestion made by DeGroote and Wirtel[56] involved the use of sodium petroleum sulphonates with a modified fatty acid partially saponified with ammonium hydroxide, and a hydrophobe solvent such as kerosene.

TEXTILE USES OF SULPHONIC ACIDS

Petroleum sulphonic acids have been suggested as wetting agents in dyeing operations, particularly when dyeing from an acid bath.[57] Under such conditions the fatty acid soaps break to fatty acids and sodium salts of the stronger acid present, the fatty acid interfering with, rather than aiding leveling of the dyestuff. The sulphonic acid wetting agents are stable under acid conditions, and efficient leveling action is said to be obtained. To prepare such an agent, Lievre[58] recommends that the oils present first be removed from the neutralized solutions obtained from acid sludge by steam distillation. The product is acidified with sulphuric acid and redistilled to remove any volatile impurities that may be formed. The refined acids are then dried and may be employed as wetting agents. MacLaren[59] reported that the sulphonation products of a specially prepared cracked distillate boiling above 230°C. are best suited to the preparation of wetting agents. The heavy "pressure tar" residue from high-pressure, high-temperature cracking stills is distilled, and the fraction boiling above 230°C. collected. According to this investigator, the material should have a sulphuric absorption between 12 and 20 per cent, a hexane solubility of 99.8 to 100 per cent, and less than half of one per cent of carbon residue. This heavy mixture is sulphonated in a cooled mixer, maintaining the temperature below 100°C. The reaction takes place almost instantaneously, to produce yields of sulphonic acids as high as 55 to 70 per cent. Baddiley and Chapman[60] have also found that best results are obtained from wetting agents composed of the sulphonation products of oils boiling above 230°C. However, they obtain their sulphonatable material from a sulphur dioxide extract boiling above this temperature rather than from a cracked, refined distillate. Field[61] uses a slightly lighter sulphur dioxide extract derived from a kerosene distillate. The extract in this case boils in the range 180 to 280°C. and according to the investigator is almost entirely composed of aromatic and unsaturated hydrocarbons. These have a high sulphuric acid absorption, but it is recommended that in the sulphonation, sulphuric acid of strength not greater than 100 per cent be used, and further, that the amount of acid be insufficient to bring about complete sulphonation of all sulphonatable compounds, since it is believed that the more readily sulphonated compounds are more satisfactory both as wetting agents and as detergent compositions. May, Brodersen and Waldmüller[62] find that the low-boiling mineral oils can be sulphonated to produce wetting agents that are useful in a somewhat different field. Added to mercerizing lyes, these lighter sulphonates improve the wetting properties of the lyes with a reported improvement in the finish of the textiles treated.

Various investigators have proposed that certain other compounds be added to the petroleum sulphonate wetting agents. For instance, such substances as benzene- or naphthalene-sulphonic acids have been suggested by Todd,[63] who reports that such compositions yield wetting agents readily soluble in cold water. Linder and Zickermann[64] propose that a mixture of a higher boiling mineral oil with an aliphatic alcohol or carboxylic acid (of not more than 10 carbon atoms) or with phenols be treated with 100 to 200 per cent of the calculated quantity of a strong sulphonating and dehydrating agent, such as chlorosulphonic acid. The products are said to be effective wetting agents.

Kennedy[65] has suggested a method of standardized classification to make possible an intelligible evaluation of various wetting agents. He proposes that the agent be rated on the basis of (a) the time required for pieces of cloth (1 cm. square) to sink in a solution containing the wetting agent, (b) the surface tension effect as measured by capillary rise, (c) the stability to hard water, (d) estimation of the fatty acid content and (e) a determination of Herbig's number.[66]

The mineral oil sulphonates have been suggested as media for carrying protective lubricants for use on yarns. Thus, Bouhuys[67] employs a mixture of mineral oil, mineral oil sulphonates, potassium soap, triethanolamine oleate and a soap-solvent, e.g., diethylene glycol, for this purpose. Such a composition does not have to be removed before the dyeing operation. On the other hand, Reddish[68] has proposed a composition that, while it is not left on the fibers during dyeing, is capable of a "self-scouring" action so that no outside agent need be employed to remove it. Refined mahogany sulphonates freed of entrained neutral oil components are used to make water-soluble a mineral white oil which acts as the lubricant. The proportions of sulphonates may vary from 7½ to 25 per cent of the oil-mahogany sulphonate mixture. According to this investigator, the resultant oil is a satisfactory lubricant for weaving, spinning or knitting operations, filming over the fibers or absorbed by the fibers very readily due to the low interfacial tension between the oil and the textile fiber. Furthermore, the oil can be removed at any time by immersion in water without the use of fatty acid detergents or alkalies. Since the oil is stable, any traces that may linger are not affected by the dyeing operation, nor do they inhibit dyeing or wetting out of the fabric or become rancid in stored cloth and thus give rise to offensive odors.

[68] W. T. Reddish, U. S. P. 1,909,721, May 16, 1933, to Twitchell Process Co.; *Brit. Chem. Abs.* **B**, 1934, 188; *Chem. Abs.*, 1933, **27**, 3834.

Reddish[69] has also suggested mahogany sulphonates as an aid to alkali used in boiling out the naturally present oil and waxes in cotton, jute and similar materials. Removal of these bodies is necessary since they render the fibers water-repellent and hence resistant to bleaching and dyeing. The addition of 0.1 to 2.0 per cent of refined mahogany sulphonates to the alkali bath serves as an activator. This is said to make the process more rapid and correspondingly milder, since the need of pressure-boiling or strong alkalies is obviated.

INSECTICIDES

As a wetting agent and vehicle in insecticides the petroleum sulphonates have several advantages. Petrov, Isachenko and Goritzkaya[70] have shown that the mixed petroleum sulphonates and mineral oils (Kontakt) are more toxic than nicotine sulphate and casein in hard water. The maximum mortality (of the insects) obtained using nicotine sulphate, soap, casein and water was 32 per cent, while with a nicotine solution one-fifth as strong plus 0.5 per cent of Kontakt, a 45 per cent mortality was recorded. A Kontakt solution (1.5 per cent) caused a 25 per cent mortality. Hessle[71] has proposed a spray consisting of non-toxic hydrocarbon oils, and an aqueous solution of toxic sulphones and sulphonates from acid sludge. A number of similar insecticides have been described by Savel'ev.[72] These are formulated as concentrates to be mixed with water and are based largely on green acids as emulsifying agents mixed with various petroleum fractions (such as kerosene, lubricating oil or the like).

Another proposal[72a] is to dissolve sulphur dioxide in a mineral (or castor) oil containing mahogany acids. The composition may be emulsified with water. Volck[73] prefers an aqueous solution of a fatty acid soap in which are dissolved sufficient free fatty acid to render the solution neutral, casein and salts of petroleum sulphonic acids.

Martin[73a] finds that petroleum calcium γ-sulphonates are effective spray

spreading agents when used in a concentration of 2 pounds per 100 gallons of spray solution. The γ-sulphonates are satisfactory in conjunction with any toxic agent now employed in practice as spreader agents, and are also useful as emulsifying agents in preparing petroleum oil-lead arsenate sprays. The β-sulphonates have excellent spreading properties, but are ineffective in the presence of copper, lead or calcium salts due to the formation and precipitation of the heavy-metal compounds.

Peairs and Gould[74] report that nicotine sulphate and Penetrol (a commercial sulphonated oxidized petroleum oil preparation) was the most successful insecticide tested for controlling the pistol case-bearer.

Grant[75] has suggested that pyrethrum or derris be extracted in a solvent composed of kerosene or light lubricating oil (31 parts), oil soluble sulphonates (18.4 parts) and water (2 parts). This solvent solution can be modified by the addition of isopropyl or higher alcohols. The mixture is said to be advantageous in that it is not sensitive to the presence of water in the vegetable matter being extracted, and can, in consequence, be used in making insecticide concentrates from moist materials.

Marx and Brodersen[76] have prepared a fungicide employing mineral oil sulphonates and dispersed sulphur.

MISCELLANEOUS USES OF PETROLEUM SULPHONATES

Fedotov[77] pointed out some years ago that ammonium sulphate and a mixture of alkali and alkaline earth metal sulphonates would serve as a leather softener in the tanning industry, and that in the chrome tanning process the same mixture would serve as a reducing agent. Later Fridlyand[78] tested this suggested process and reported that it gave good results and could be used in place of the usual sulphite on calf skins. Bazarova[79] also investigated the possibilities of the petroleum oil sulphonates as reducing agents in chrome tanning to replace the glucose solution. His results showed that these substances (Kontakt) worked well, the reduction proceeding as follows:

$$
\begin{aligned}
&12K_2Cr_2O_7 + 11H_2SO_4 + C_{14}H_{16}SO_3 + 17H_2O \longrightarrow 12Cr_2(OH)_6 + 14CO_2 + 12K_2SO_4\\
&12K_2Cr_2O_7 + 23H_2SO_4 + C_{14}H_{16}SO_3 \longrightarrow 12K_2SO_4 + 12Cr_2(OH)_4SO_4 + 14CO_2 + 7H_2O\\
&12K_2Cr_2O_7 + 35H_2SO_4 + C_{14}H_{16}SO_3 \longrightarrow 12K_2SO_4 + 24Cr(OH)SO_4 + 14CO_2 + 31H_2O\\
&12K_2Cr_2O_7 + 47H_2SO_4 + C_{11}H_{16}SO_3 \longrightarrow 12K_2SO_4 + 12Cr_2(SO_4)_3 + 14CO_2 + 55H_2O
\end{aligned}
$$

It is reported[80] that petroleum sulphonates obtained in manufacturing white oils will serve as solvent activators to speed the mastication of rubber, if added to such a vehicle as mineral seal oil. King and King reported that petroleum sulphonates mixed with mineral seal oil serves as a thermoplasticizing compound for use with rubber.[81] Gorsuch and Kinney[82] propose an emulsion of glycerol, alcohol, mineral oil, rosin soap and mahogany sulphonates to prevent rubber sticking during vulcanization.

A number of lubricating compositions have been prepared with petroleum sulphonates, such as an extreme pressure lubricant made from a high-quality lubricating stock by incorporation of a lead salt of the oil-soluble mahogany sulphonates.[83] Adding a sodium salt of a mahogany sulphonate together with 5 to 30 per cent of a calcium soap, 15 to 20 per cent of petrolatum to a hydrocarbon oil and sufficient water for emulsification produces a stable, non-sweating grease.[84] Gay[85] reports a stable cutting-oil emulsion made up of 1 part of mahogany sulphonates, 0.5 part of alkali metal rosin soaps together with mineral oil and not more than 14.5 per cent of water. Brunstrum and Hilliker[86] compound a plug valve lubricant (for steam lines) from graphite, anhydrous calcium soap and a lead mahogany sulphonate soap.

The emulsive powers of the sulphonates make them useful in polishing compounds. Lewers[87] prepares a water-in-oil polishing wax from 30 parts of carnauba wax, 20 parts of paraffin wax, 120 parts of naphtha, 4 parts of heavy mineral oil and 10 parts of oil-soluble petroleum sulphonates in 300 parts of water. Mahogany sulphonates have been employed[88] in making a liquid coating compound from casein, glue or other water-insoluble colloid and oil with pigments or fillers.

Water-soluble petroleum sulphonates have been suggested as dust fixatives. The sulphonates (as sodium salts) in 15 per cent aqueous solution are mixed with a hygroscopic agent such as glycerol and a plasticizing agent such as glucose. This mixture is sprayed on the dust, and it is reported that the surface becomes covered with a solid layer of cemented dust.[89]

Oil-soluble dyes can be prepared from water-soluble dyestuffs with the aid of mahogany sulphonates. This has been accomplished in two ways: by forming a true compound between a basic-reacting, water-soluble dye; and by causing the oil-soluble sulphonate to absorb a quantity of a concentrated aqueous solution of the dyestuff. In the former process the dye (Victoria Green, Bismarck Brown or Methylene Blue, for example) is reacted in an acidified aqueous solution with the sulphonic acid (usually present as an alkali metal salt).[90] In the latter method, no true compound is formed, but the mahogany sulphonate acts to form an optically clear dispersion of a water-soluble dye throughout oils, fats and waxes. According to Straus[91] oil-soluble dyes and shades are restricted in number and variety. They are, furthermore, less resistant to the action of light than are available water-soluble colors. Sulphonic dispersion makes more varied water soluble dyes available as oil-soluble dyes. The dispersion is prepared, for example, by grinding together two parts of Patent Blue A, Color Index 714, 10 parts of purified, oil-soluble mineral oil sulphonate, 12 parts of mineral white oil and 10 parts of water. The action in the present case depends on the fact that mahogany sulphonates are capable of absorbing a certain quantity of water without losing the property of dissolving in oil, and that this absorbed water may be present as a concentrated solution of a water-soluble dyestuff.

In combination with fatty acids, such as stearic, mahogany sulphonates have been found useful in preventing foaming in emulsions. Buc[92] suggests a combination of one part of stearic acid, 99 parts of oil-soluble sulphonates and 500 parts of heavy mineral white oil. This combination may be added to 5,000 parts of water to form a stable, non-foaming emulsion. By incorporating 3 per cent of mahogany sulphonates with 97 per cent of mineral white oils, Mathias[93] makes a foam-preventing mixture for use in beet-sugar refining. Bird[94] reports that the water-soluble sulphonic acids may be added to aqueous solutions, such as sugar solutions, to precipitate coloring matter and substances rendering the solution cloudy. The water soluble acids are added, to bring about precipitation of their insoluble alkaline earth salts. The salts come out of solution in such a form as to be highly adsorbent, carrying with them coloring matter present in the solution.

McIntyre and Higgins[95] report that a specially prepared mahogany sulphonate can be treated to meet the government requirements for a fat-denaturant. Acid oils obtained in refining are treated with 5 to 30 pounds of 98 per cent sulphuric acid for each 50 gallons of oil, and the sludge settled out. The latter is washed with about an equal amount of water, and this is then drawn off leaving the sulphonates. Neutralized with sodium hydroxide, washed with water and reduced, they are mixed with the fats to be denatured with or without the application of heat.

Medicinal products have been prepared from sulphur-bearing mineral or shale oils, particularly those containing more than 2 per cent of sulphur. Wernicke[96] recommends that these oils be refined under such conditions as will not reduce the sulphur content, e.g., with alkali solution, sulphuric acid of 40 to 75 per cent concentration, aluminum chloride or bleaching earth. Sulphonation is then effected at a low temperature, yielding transparent products of alleged therapeutic value.[97] Hessle[98] makes a sulphonated product reputed to be of therapeutic value by reacting a hydrocarbon oil with sulphur in the presence of an iron oxide catalyst. This product is treated with oleum (30 per cent free sulphur trioxide), and the resulting sulphonated compounds precipitated. After washing with brine they are extracted with benzene, neutralized with alkali hydroxide and the solvent evaporated. The resultant product is a reducing agent, and if specially dehydrated in a vacuum dryer produces a fluffy yellow powder inflammable in air.

According to Nazarov and Khain[99] petroleum sulphonic acids are effective as catalysts in preparing esters, being as effective as sulphuric acid in this synthesis. Isopropyl acetate was made by reacting the alcohol and acetic acid at 105 to 110°C. at a feed rate of 1 cc. per minute and an alcohol-acid ratio of 4.22 to 1.

[97] These sulphur-bearing oils are known by the general term "ichthyols," particularly those containing very considerable percentages of organic sulphur. J. A. Riddick (*Field and Lab.*, 1936, **4**, 33; *Chem. Abs.*, 1936, **30**, 5365) reports that such an oil may be obtained by the destructive distillation of a bituminous rock found near Burnet, Texas. The oil so obtained is dark red, and contains about 10 per cent of organic sulphur. The oil is sulphonated and the resulting acids neutralized with ammonium hydroxide to produce the ichthyol of commerce. The product so obtained contains about 48 per cent of water, 5.5 to 6.3 per cent ammonium sulphate, and the remainder is the ammonium ichthyolsulphonate. Riddick gives some discussion of the therapeutic value of these oils. For further discussion of the preparation of these materials, see Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., Inc., New York, 1934.

The yield amounted to 97 per cent on the anhydrous acetic acid or 94 per cent on the original material. With technical grade materials, the yield falls to 73 per cent on the anhydrous acid (42 per cent on the technical 58 per cent acetic acid). Only 8.2 g. of the petroleum sulphonates were used per kilogram of the acetate. Similar experiments with secondary butyl and amyl alcohols gave equally good results.

Virobyantz[100] reports that treatment of a petroleum fraction (containing aromatics) with 97 to 99 per cent sulphuric acid for five hours, followed by settling and separation of the sulphonic acids, makes possible a 90 per cent recovery of aromatics. The sulphonic acids are readily decomposed by dilution with water and distillation with superheated steam. Hydrolysis begins at 140°C. and is practically complete at 210°C. The recovered aromatics afterwards are freed of acidic bodies and dried.

Petrov[101] reports that high molecular weight sulphonic acids can be condensed with aldehydes, in the presence of aromatic amines, to form resins applicable in varnishes and lacquers. Langedijk[102] has prepared the heavy metal salts of petroleum oil sulphonates and finds them available as siccatives for use in paints and varnishes. A brushless shaving cream, described by Ferguson,[102a] is composed of water, stearic acid, a fatty oil and the water-soluble salt of a sulphonated (or sulphated) aliphatic hydrocarbon. The latter should contain 10 to 18 carbon atoms per molecule.

Another use suggested for sulphonic acids is as a coagulating agent for carbon in the recovery of sulphuric acid from acid sludge.[103]

SULPHONATION OF OLEFINS

Though the discussion in this chapter has been primarily the sulphonation of paraffin and aromatic hydrocarbons of petroleum, the sulphonation and sulphation of olefins simultaneously present is necessarily of interest and industrially of increasing importance. Some of the reactions of the olefins with sulphuric acid (sulphation) have been discussed in other chapters,[103a] and attention now will be directed only to sulphonation reactions.

When ethylene is absorbed in sulphuric acid of more than 100 per cent concentration, carbyl sulphate is formed.[104] This substance is becoming of greater importance as uses are developed for it and its hydrolysis product, isethionic acid. Carbyl sulphate itself can be converted to acetic acid according to Merley and Spring[105] by a process involving neutralization and hydrolysis. The sulphate is hydrolyzed by the addition of water, and the solution neutralized with caustic soda. Some of the sodium sulphate formed is separated out by cooling and the liquor is then heated with calcium hydroxide and excess sodium hydroxide. Sodium acetate thus formed is acidified with the hydrolyzed carbyl sulphate liquors from the first step of the process and fractionally distilled to yield free acetic acid. The hydrolysis product of carbyl sulphate, isethionic acid, is the source of the sulphonate group in an important class of sulphonate detergents, the Igepons.

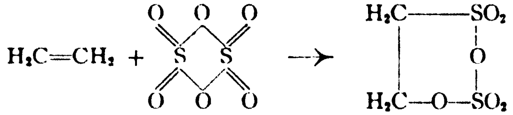
Michael and Weiner[106] have investigated the action of oleum on ethylene in some detail and concluded from their results that the reaction proceeds either (1) by the addition of pyrosulphuric acid (present in equilibrium with sulphuric acid) according to the mechanism:

$$H_2C{=}CH_2 + HOSO_2OSO_2OH \longrightarrow HO_3SCH_2CH_2OSO_3H$$

to produce ethionic acid; or (2) when the anhydride is present in excess (since sulphur trioxide cannot add directly) the dimer, S_2O_6, present in equilibrium in the solution, adds to form carbyl sulphate as follows:[107]



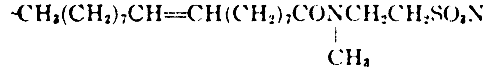
Adams, Eatough and Marvel[108] report that the reaction product of an olefin and sulphur trioxide can be transformed by concentrated hydrogen chloride into a chloroalkane sulphonic acid, such as chloroethanesulphonic acid.

THE SULPHO DETERGENTS

Two principal types of these detergents are being marketed: the true sulphonates and the sulphuric acid esters of high molecular weight alcohols (produced by hydrogenation of the corresponding fatty acids).[109] Representative of the former class are the Igepons A and T. Igepon A is the condensation product of isethionic acid and oleic acid corresponding to the formula,

$$CH_3(CH_2)_7CH{=}CH(CH_2)_7COOCH_2CH_2SO_3Na$$

and is reported to be a good detergent, fairly stable to acid solutions though subject to hydrolytic splitting at the carboxyl group in alkaline solutions. Igepon T was developed to overcome this fault and stands up better in both alkaline and acid solutions.[109a] The formula of Igepon T is,



$$CH_3(CH_2)_7CH{=}CH(CH_2)_7CO\underset{\displaystyle CH_3}{\underset{|}{N}}CH_2CH_2SO_3Na$$

Numerous methods of producing the sulphonated substances have been proposed. One method comprises treating aliphatic or cycloaliphatic compounds with sulphuric acid or other sulphonating agent in the presence of an organic solvent inert to the acid. Thus, if carbon tetrachloride is used, the reaction products are allowed to settle and the excess sulphuric acid is found in the lower layer, the solvent carrying the sulphonation products in the upper layer.[110]

Fulton and Vesterdal[111] prepared sulphate detergents which were said to be suitable for use with sea water. A mixture of olefins (containing octenes and higher members) obtained from oil cracking is treated with fuming sulphuric acid below 5°C. After reaction, the mixture is made alkaline and heated in order to decompose any unstable compounds present. The desired soap is then separated from this mixture. A flow sheet of their procedure is given in Fig. 261.

---

[106] A. Michael and N. Weiner, *J.A.C.S.*, 1936, 58, 294; *Chem. Abs.*, 1936, 30, 2922.

[107] It should be noted that these investigators do not agree with the mechanism proposed by H. Wieland and E. Sakellarios (*Ber.*, 1920, 53, 203; *Chem. Abs.*, 1920, 14, 2636) who suggest that strong inorganic acids add as basic addenda —OH and acidic radicals. Thus, sulphuric acid would add as —OH and —SO_3H.

[109] To simplify discussion of these high molecular weight alcohols, the name "hymolal" has been suggested (*Ind. Eng. Chem., News Edition*, 1934, 12, 98). The wetting and cleansing agents derived from them are "hymolal salts," of which class sodium lauryl sulphate is an example. See also. Swiss P. 156,087, 1932, to H. Th. Böhme A.-G.; British P. 354,851, 1932; *Chem. Abs.*, 1932, 26, 5773; and British P. 357,649, 1932, to H. Th. Böhme A.-G.; *Chem. Abs.*, 1932, 26, 6083; *Brit. Chem. Abs.* B, 1932, 56.

On the other hand a sulphonic acid can be made, in addition to methods previously mentioned, by oxidation of the corresponding thiosulphate. If sodium dodecanethiosulphate is oxidized with sodium permanganate, aqueous nitric acid or hydrogen peroxide, the corresponding sodium dodecanesulphonate can be obtained.[112] An analogous method suggested by Keller[113] uses a sulphurated technical mixture of paraffin hydrocarbons of 8 or more carbon atoms (made by treating a mixture of chlorinated paraffinic compounds with an alcoholic solution of potassium sulphide). This mixture is treated with an oxidizing agent such as nitric acid, hydrogen peroxide or a dichromate to produce the corresponding sulphonic acids. Partially oxidized stages of this reaction yield acids said to have good emulsive power.

[112] British P. 439,177, 1934, to Henkel & Cie. G.m.b.H.; *Brit. Chem. Abs.* B, 1936, 138.

[113] K. Keller, U. S. P. 1,925,191, Sept. 5, 1933, to General Aniline Works; *Chem. Abs.*, 1933, 27, 5337.

Investigations of the detergent properties of Igepon A and T carried out by Boedeker[114] showed that 3 per cent solutions of these substances contained no colloidal particles and behaved as true solutions, while similar warm solutions of sodium stearate and oleate contained particles visible in the ultramicroscope. Cooling the stearate solution below 20°C. caused it to gel due to the formation of closely interlocked needle crystals. A 20 per cent solution of sodium oleate showed similar properties. The addition of 16 per cent (by weight on the sodium stearate or oleate) of Igepon A to such a solution prevents the formation and precipitation of insoluble calcium and magnesium soaps in hard water.

Lederer[115] found that Igepon A and T show emulsification, foaming and surface tension lowering properties similar to those of soaps although in equally concentrated solutions the interfacial tension with oil is much lower when the Igepons are used than under the action of soaps. This investigator reports the percentage composition of the Igepons as follows:

	Igepon A %	Igepon T %
Active substance	45	33.5
Soap	4	2.5
Salts	16	8.0
Water	35	56.0
Molecular weight	412	425

Though general application of the sulpho detergents may be limited by their higher cost, many special uses have been developed where their desirable qualities more than offset this factor. Special formations as flakes or filaments[116] aid in rapid solution. Their ability to resist acid is taken advantage of in removing pitch (originating from the branding of sheep) from raw wool. The latter is treated in a fulling mill with one of these detergents, and when the pitch has been removed the solution is withdrawn and fulling carried out as usual.[117] By using a water-soluble alcohol, dilute acetic acid and one of the acid-stable sulpho detergents, colored carpets can be cleaned and their brightness restored without removing naturally present protective oils and fats.[118]

Representative of the second class of sulpho detergents, i.e., those containing the sulphate group, is sodium oleyl sulphate:

$$CH_3(CH_2)_7CH{=}CH(CH_2)_7CH_2OSO_3Na$$

or sodium lauryl sulphate:

$$CH_3(CH_2)_{10}CH_2OSO_3Na$$

The sulphated products are made from saturated alcohols (having 10 to 14 carbon atoms) which in turn are obtained by hydrogenating cocoanut or palm kernel oils. The sodium salt of the sulphated product is marketed in the textile trade as "Gardinol WA." The oleyl sulphate is made by sulphating the alcohol (generally produced by hydrogenating material obtained from sperm oil), but in this process it is difficult to avoid some sulphation of the double bond, so that the technical sodium salt is generally a mixture of the sulphate ester and the sulphonate.[119] Siebenbürger[120] finds, however, that the sulphation can be directed to a certain

extent. If the sulphonation be carried out by treating the higher alcohol to be sulphonated with the addition product of a liquid organic base (such as pyridine or dimethylaniline) and sulphur trioxide, practically all sulphonation will take place at the hydroxyl group of the alcohol, according to this investigator. From analytical figures, it was found that the product obtained by this type of procedure consists only of the sulphuric acid ester salt, while the double-bonded alcohols might be sulphated similarly without addition at the unsaturated linkage. The properties of these sulphate detergents parallel fairly closely those of the sulphonate detergents

Courtesy Industrial and Engineering Chemistry

and are used in much the same ways as wetting and detergent agents in textile uses and as emulsifying and demulsifying agents. Thus, Neville and Jeanson[121] reported that the sulpho detergents react similarly in their absorption rates in alkaline and acidic solutions and in their effects on dye absorption. Using wool as a standard fabric and working with both Gardinol CA (a sulphate) and Igepon T (a sulphonate), it was found that these substances may, under varying conditions, aid or retard dye absorption, while the absorption of the wetting agent itself varies widely with the *p*H value of the solution, being so rapidly absorbed in strongly acid solutions as to be uneconomic.

Aside from the sulphation of the high molecular weight alcohols, other methods have been proposed for producing the sulphated type of aliphatic substance. Thus Kalischer and Biehler[122] make the sulphated aliphatic acids and esters by treating the corresponding aliphatic hydroxy or unsaturated acid with the product obtained by reacting acetic anhydride with oleum. Bertsch[123] suggests treating similar aliphatic acids, such as ricinoleic, with a low-weight alcohol such as isobutyl, and a sulphating agent, or, alternatively, using isobutylsulphuric acid as sulphating agent.

The detergent action of the sulphates has been used in de-inking waste paper. It is proposed that a substance such as sodium lauryl sulphate be used with a halogenated hydrocarbon solvent or with fuller's earth. The treatment may be carried out in a hollander, the solution separated for reuse, and the washed pulp remade into paper.[124] Leathermann[125] uses the wetting properties of the sulphate salts in fireproofing a fabric. The cloth is saturated with a 1 per cent solution of sodium lauryl sulphate, wrung out and impregnated with sodium stannate. After drying it is immersed in an aqueous ferric chloride solution. Washed and re-dried, it is then impregnated with chlorinated rubber and can be dyed if desired. Ellis[126] reports that the solubility of sulphate detergents in water, as well as their cleansing action, is increased by incorporation of water-soluble mineral-oil sludge sulphonates. He proposes that the sulphate derivatives be prepared from alcohols obtained on the oxidation of paraffin wax. The detergent compositions may be admixed also with hydroformed or hydrofined naphthas.

The sulphates are frequently used as constituents in agents designed to break water-in-oil emulsions. An ammonium salt of oleic hydrogen sulphate has been proposed for this purpose[127] and also such substances as the sulphuric acid ester of a high molecular weight alcohol (of from 12 to 26 carbon atoms)[128] or the sodium salt of a sulphate derived from tetradecyl alcohol.[129]

Chapter 47

Chemical Action of Nitric Acid and Various Other Reagents on Saturated Hydrocarbons

The saturated paraffin and cycloparaffin hydrocarbons have often been regarded as very stable and inert substances which remain unaffected by most chemical reagents since all the carbon atoms in such hydrocarbons have their valences satisfied by hydrogen and other carbon atoms and therefore they would not be expected to undergo the numerous addition reactions characteristic of olefins and acetylenes. The results of many investigators have indicated, however, that the progressively higher members in a homologous series of the saturated hydrocarbons, and especially some of the branched-chain members, become more reactive toward many of the reagents which act upon aromatic hydrocarbons. Furthermore, the paraffins as a rule are especially susceptible to pyrolytic decomposition which not only results in the production of unsaturated and saturated compounds of lower molecular weight, but also the intermediate formation of free radicals which are usually much more reactive than the corresponding hydrocarbons.

Even after it was generally conceded that the higher paraffins were not inert bodies, this was still more or less the belief with respect to the lower (gaseous) members of the series, because, even though many of the liquid and solid paraffins were directly nitrated as early as 1880, this reaction had not been effected with the lower members (methane, ethane, propane and butane) as late as 1932. However, these lower members were successfully nitrated, in the vapor phase, about 1933. Apparently the gaseous cycloparaffins have not as yet been nitrated. Another reaction which appears to be of increasing importance to the paraffin hydrocarbons is the Friedel-Crafts reaction, which for many years was believed to be restricted entirely to aromatic compounds. All these and other factors should serve to create additional interest in the chemistry of the paraffin hydrocarbons in the future.

NITRATION OF PARAFFIN AND CYCLOPARAFFIN HYDROCARBONS

Although considerable work has been done on the direct nitration of the liquid and solid paraffin hydrocarbons since Meyer and Stüber[1] first prepared nitroparaffins in 1872 (from alkyl iodides and silver nitrite) it was not until about 1933 that direct nitration of the gaseous paraffins was successfully accomplished. Hass, Hodge and Vanderbilt[2] investigated the reaction of methane, ethane, propane and the two butanes with nitric acid in the vapor phase. Of these, they were able to nitrate all except methane. Small amounts of nitromethane were formed, however, during the nitration of the immediate homologues of methane.

P. 2,071,122, Feb. 16, 1937, to Purdue Research Foundation.

In the apparatus as shown in Fig. 264, hydrocarbon gases pass, at the rate of 150 liters per hour, through the flowmeter and then bubble through hot, concentrated nitric acid, the latter being added to the flask, as needed, from the dropping funnel as indicated. The mixed vapors of nitric acid and hydrocarbon then pass into the glass reactor (consisting of a series of U-bends) immersed in a eutectic mixture (molten) of sodium nitrite and potassium nitrate. The products issuing therefrom are recovered in condensers and a fog trap.

Hass and co-workers carried out their nitrations, both in batch and continuous processes, using concentrated nitric acid and the hydrocarbons under various pressures and at temperatures above the critical temperatures of the reactants so as to overcome certain difficulties such as immiscibility of the materials used. In the continuous process the hydrocarbon vapors were bubbled through hot concentrated nitric acid and the mixed vapors conducted into a reaction tube which was immersed in a molten salt bath heated to the desired temperature. After reaction the products were led into a condenser unit and finally into a fog trap and later separated by fractional distillation (Fig. 265). Oxidation always accompanied nitration and this was believed to result in the conversion of the paraffins to fatty acids which were then nitrated with the subsequent loss of carbon dioxide to give lower nitroparaffins. They also found that the isomeric products formed by nitration varied considerably with the temperature and permitted a certain measure of selectivity. For example, at 150°C. in sealed tubes, 2-methyl-2-nitropropane was the only nitro compound resulting from the nitration of isobutane, but, under atmospheric pressure and at 420°C., this isomer comprised only 7 per cent of the nitro compounds formed. No catalyst was found which aided nitration. Silica gel and platinum promoted oxidation rather than nitration.

FIG. 264.—Apparatus for Nitration of Gaseous Paraffin Hydrocarbons at Atmospheric Pressure. (H. B. Hass, E. B. Hodge and B. M. Vanderbilt)

The apparatus as shown in Fig. 265 operates in a manner similar to that of Fig. 264 except that superatmospheric pressures are employed. The main portion of the apparatus, including the reaction coil, however, is constructed of stainless steel instead of glass. The reactants (hydrocarbon and concentrated nitric acid) are introduced under pressure, the latter material being supplied by a stainless-steel pump. The products are recovered by condensation.

FIG. 265.—Apparatus for Vapor-Phase Nitration of Paraffin Hydrocarbons at Superatmospheric Pressure. (H. B. Hass, E. B. Hodge and B. M. Vanderbilt)

In Table 204 are shown the results of some of their experiments using a 2:1 molar mixture of hydrocarbon and nitric acid. The yields in the last column are based on the nitric acid used.

TABLE 204.—*Nitration of Gaseous Paraffins, 420°C., 1 Atm.*

Hydrocarbon	Acetone	Nitromethane	Nitroethane	1-Nitropropane	2-Nitropropane	1-Nitrobutane	2-Nitrobutane	1-Nitroisobutane	2-Nitroisobutane	Yields
						Per Cent				
Methane . .	—	—	—	—	—	—	—	—	—	0
Ethane	—	10 20	80-90	—	—	—	—	—	—	9
Propane . . .	—	9	(26?)	32	33	—	—	—	—	21
Butane	—	6	12	5	—	27	50	—	—	28
Isobutane . .	5	3	—	—	20	—	—	65	7	25

In Figs. 266, 267, and 268, are shown the rectification curves obtained with the products resulting from the nitration of isobutane, butane, and propane, respectively, at 420°C. and atmospheric pressure. Since the distillations were carried out under reduced pressure, the boiling points appearing on the curves have been corrected to 760 mm.

Although the direct nitration of methane appears not to have been attained, higher nitro compounds of methane have been prepared by nitration of compounds in which the methyl group occurs, for instance acetic anhydride. Krauz and Stepanek[3] described a process which is said to give yields of tetranitromethane as high as 95 per cent.

Fuming nitric acid, 65 parts, was distilled with 25 parts of phosphorus pentoxide, and the resulting nitrogen pentoxide added fo 100 parts of acetic anhydride. The mixing was accomplished very slowly, with constant stirring, while the temperature was maintained at 0°C. by ice cooling. The mix was then permitted to stand in ice water for 24 hours, and subsequently at laboratory temperature for 8 days. At the end of this period, it was poured into a large excess of cold water. The oil resulting was immediately separated, and washed with a 0.5 per cent aqueous solution of sodium bicarbonate, then with pure water, and dried with anhydrous sodium sulphate. By freezing out at 13°C., a yield of 95 per cent was obtained, the investigators reported. An attempt was made to prepare tetranitromethane by nitration of dimethylketone, but Krauz and Stepanek report obtaining a silver salt during the process which was unusually explosive. It was thought to be a salt of acetylmethylnitrolic acid.

Wyler[4] reports an analogous process of nitrating acetic anhydride to tetranitromethane, but this investigator finds that nitric acid may be used in place of nitrogen pentoxide, if catalysts such as phosphoric acid, phosphorus pentachloride, sulphuric acid, or sulphuryl chloride are present.

Nitration of many of the liquid paraffin hydrocarbons (for example, the pentanes, hexanes and heptanes) can be effected with nitric or fuming nitric acid.[5] Aliev and Gutuirya[6] found that saturated hydrocarbons do not react with hydrated aluminum nitrate [$Al(NO_3)_3$ $9H_2O$] at 95-100°C. Konowalow,[7] however, nitrated 2,7-dimethyloctane (possibly at a higher temperature) by heating it with this aluminum salt in an open vessel. Shoruigin and Topchiev[8] treated hexane, at 10-80°C., with nitrogen tetroxide (N_2O_4) diluted with carbon dioxide and obtained small yields (5-10 per cent) of 2-nitrohexane. Ultraviolet light was found to have no effect on the reaction. When toluene was nitrated under these conditions phenylnitromethane

and the ring-substituted mononitrotoluenes were obtained. The total yield of nitro compounds was increased by the use of ultraviolet light, although the relative proportions of the two types of products remained practically unchanged. They found also that cyclohexane reacted, at 30°C. and 80°C., with nitrogen tetroxide (N_2O_4) diluted with carbon dioxide, to give 20-25 per cent yields of nitrocyclohexane, and that the reaction was unaffected by ultraviolet light. Platonov and Shaikind[9] treated *n*-pentane, *n*-hexane, and *n*-heptane with nitric oxide (NO) at 450-500°C., using as catalyst kaolin mixed with the oxides of aluminum, cerium, and thorium. The products consisted of ammonia, nitric oxide, nitrogen, carbon monoxide, methane and unsaturated hydrocarbons. At 250-300°C., in the presence of vanadium pentoxide or platinum black, as catalysts, water, carbon monoxide, nitrogen, and unchanged hydrocarbons were formed. No carboxylic acids were detected among any of the products.[10]

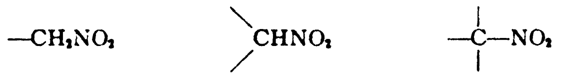
[9] M. S. Platonov and S. P. Shaikind, *J. Gen. Chem.* (*U.S.S.R.*), 1934, **4**, 434; *Brit. Chem. Abs.* **A**, 1934, 1329.

[10] R. H. McKee and R. H. Wilhelm (*Ind. Eng. Chem.*, 1936, **28**, 662; *Chem. Abs.*, 1936, **30**, 8180) report that nitrogen dioxide may be employed in nitrating benzene in the vapor phase, and state that in this reaction silica gel serves effectively as a catalyst. Yields as high as 83 per cent (based on benzene consumed) are said to result, and the production of by-products was not found

Nametkin and Nifontova[11] nitrated highly refined fractions of Grozny and American paraffin waxes with dilute nitric acid (sp. gr. 1.075) in sealed glass tubes at 125-130°C. From this they obtained a tertiary nitro compound ($C_{24}H_{49}NO_2$) melting at 29°C., a secondary nitro compound ($C_{24}H_{49}NO_2$) melting at 45° to 48°C., and an oil consisting of a dinitro compound [$C_{24}H_{48}(NO_2)_2$]. From this they concluded that these samples of paraffin wax contained about 25-30 per cent of isoparaffins. These same investigators[12] report that dilute nitric acid acts on another paraffin wax to yield a secondary nitro compound, $C_{26}H_{53}NO_2$, a smaller amount of the tertiary compound $C_{22}H_{45}NO_2$, and some of the dinitro compound $C_{22}H_{44}(NO_2)_2$. This wax consisted largely of *n*-alkanes, with not more than 10 per cent *iso*-alkanes.

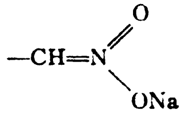
PROPERTIES OF NITRO COMPOUNDS OF PARAFFIN AND CYCLOPARAFFIN HYDROCARBONS

Of the three types of mononitro compounds, namely, primary, secondary, and tertiary, possessing the groupings shown below,

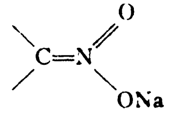


primary *secondary* *tertiary*

the first two are differentiated from the third by solubility in aqueous or alcoholic alkali solutions, in which the tertiary compounds are insoluble. This is due to the fact that the primary and secondary nitro compounds tautomerize in the presence of alkalies to the corresponding isonitroparaffins.[13] The structures of the sodium salts of these are shown below, in which form they are stable.



primary isonitro form



secondary isonitro form

If solutions of the salts of the isonitro compounds are acidified the first-formed yellow isonitro compounds

$(=C=\overset{\overset{\displaystyle O}{\|}}{N}-OH)$

rapidly change[14] to the colorless and stable normal form ($=CH-NO_2$). A study of the Raman effect of the nitromethanes[15] has substantiated the normal form as the one in which these compounds ordinarily exist.

The mononitro compounds of the lower paraffins are generally colorless liquids, possessing boiling points considerably higher than the corresponding hydrocarbons, usually distil without decomposition, and are sparingly soluble in water. The dinitro and trinitro compounds, also usually colorless, are high-boiling liquids or crystalline solids and many can be distilled with steam. Hunter and Marriott[16]

---

to be excessive. Silica gel appears to have functioned as a dehydrating catalyst, as it does in numerous other reactions (e.g., esterification of acetic acid and alcohol). The product consisted largely of mononitrobenzene, though some nitrophenol was obtained, particularly in runs conducted at temperatures above 330°C. A temperature of 310°C. and an excess of nitrogen dioxide were required for the best yields. Some nitrogen dioxide was reduced to the monoxide, hydrogen being released as water. The monoxide may be reoxidized to nitrogen dioxide, however, by air oxidation.

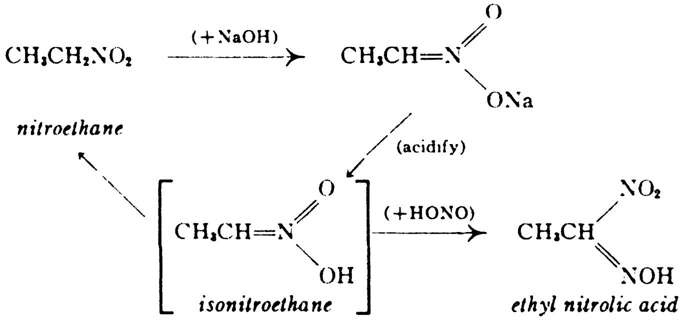
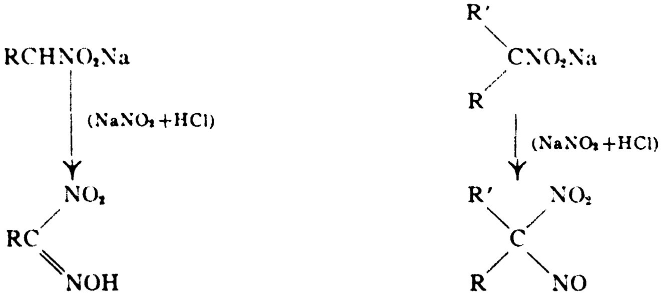
found, however, that nitrocyclohexane was somewhat unstable. Decomposition was most rapid and complete in open vessels, but occurs also in sealed tubes, yielding adipic acid in 1 to 4 weeks. Nitromethane, and some of the polynitro compounds, are not easily explosive, but Hass and co-workers[17] report that nitroethane, nitropropane, and the higher homologs are non-explosive. The corresponding mononitrates (e.g., methyl nitrate), on the other hand, are explosive according to Deniges.[18] Some of these nitric acid esters decompose explosively when warmed to yield, among other things, aldehydes and oxides of nitrogen. The rate of decomposition is, however, greatly decreased by an atmosphere of carbon dioxide. Thus, in a current of carbon dioxide, methyl nitrate, the most explosive of the series, could be distilled without explosion. The nitrates of secondary compounds, such as isopropyl nitrate, yielded the corresponding ketone and nitrogen oxides, this decomposition too being retarded by the presence of carbon dioxide.

The primary and secondary nitroparaffins are further differentiated by their ability to form nitrolic acids and pseudonitroles, respectively, when treated with alkaline solutions of sodium nitrite and subsequently acidified.[19] It has been shown that aqueous solutions of nitroethane are indifferent toward nitrous acid.[20] When freshly prepared solutions (from sodium nitroethane and hydrochloric acid), which contain isonitroethane, are used, however, a reaction occurs to give ethylnitrolic acid.



Primary nitroparaffins, with nitrous acid, give nitrolic acids which are red in solution. On the other hand, the secondary nitroparaffins yield pseudonitroles, which are blue in solution, while the tertiary nitro compounds do not react. These reactions are represented as follows:



nitrolic acid *pseudonitrole*

---

[17] H. B. Hass, E. B. Hodge, and B. M. Vanderbilt, *Ind. Eng. Chem.*, 1936, **28**, 339; *Chem. Abs.*, 1936, **30**, 2918; *J. Inst. Pet. Tech.*, 1936, **22**, 203A; *Brit. Chem. Abs.* **A**, 1936, 587.

[18] G. Deniges, *Compt. rend.*, 1936, **202**, 1998; *Chem. Abs.*, 1936, **30**, 6703; *Brit. Chem. Abs.* **A**, 1936, 1094.

[19] J. Tscherniak, *Ann.*, 1876, **180**, 166; *J.C.S.*, 1876, **29**, 503. V. Meyer, *Ann.*, 1875, **175**, 88; *J.C.S.*, 1875, **28**, 557.

[20] A. Hantzch and H. Kissel, *Ber.*, 1899, **32**, 3137; *J.C.S.*, 1900, **78** (1), 89; *Chem. Zentr.*, 1900, **1**, 115.

The nitrolic acids are colorless or yellow bodies with acidic properties. They decompose slowly at room temperature and rapidly with the aid of heat to give the corresponding carboxylic acids, nitrogen tetroxide and nitrogen. With concentrated sulphuric acid they give carboxylic acids and nitrous oxide.[21] These reactions are illustrated by the following examples:

$$2RCH(NO)NO_2 \xrightarrow[\text{(heat)}]{} 2RCOOH + NO_2 + 1\tfrac{1}{2}N_2$$

$$RCH(NO)NO_2 \xrightarrow[(H_2SO_4)]{} RCOOH + N_2O$$

On reduction with tin and hydrochloric acid,[22] or sodium amalgam and water in the cold, they yield carboxylic acids, nitrous acid, and ammonia, with the intermediate formation of hydroxylamine. Wieland[23] obtained acethydroxylamine-oxime, $HO{-}NH{-}C(CH_3){=}NOH$, by the reduction of ethylnitrolic acid with sodium amalgam. Propyl pseudonitrole yields dimethylketoxime[24] when reduced with aluminum amalgam or ammonium sulphide. On oxidation with chromic acid the pseudonitroles are converted into dinitro compounds.[25] Further, the nitrolic acids and pseudonitroles are capable of diazotizing aniline.[26] The silver salts of nitrolic acids react with alkyl iodides to form colorless esters[27] and the sodium salts esterify with acid chlorides.[28]

The products formed by reduction of the nitro compounds depend largely on the conditions of reduction. For instance, nitromethane, treated with hydrogen[29] at 150-180°C. in the presence of nickel, gives methylamine, whereas, if stannous chloride[30] is employed as the reducing agent a mixture of methylamine and methylhydroxylamine is obtained. Nitroethane,[31] and also the primary mononitro compounds of hexane, heptane, and octane[32] furnish the corresponding primary amines on reduction with iron and acetic acid. Konowalow[33] treated 2-nitrohexane with zinc and acetic acid and obtained a mixture of 2-hexylamine and hexanone-2. From 2-nitro-2,3-dimethylbutane and 2-nitro-2,5-dimethylpentane, with tin and hydrochloric acid, he prepared the corresponding amines. On the other hand, 1-nitro-2,7-dimethyloctane gave a mixture of the corresponding primary amine and the aldehyde

$$(CH_3)_2CHCH_2CH_2CH_2CH_2CH(CH_3)CHO$$

when reduced under similar conditions. 2-Nitro-2,7-dimethyloctane, with tin and hydrochloric acid, furnished the corresponding amine. The secondary nitro compound (3- or 4-nitro-2,7-dimethyloctane) yielded a mixture of the secondary amine and the ketone when reduced in this manner.

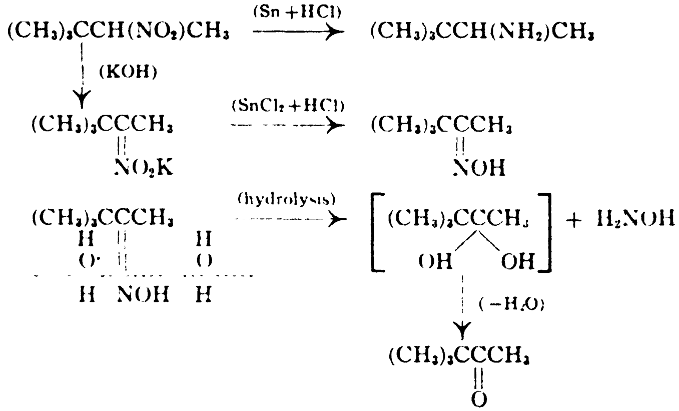
Markownikow[34] found that the reduction of 3-nitro-2,2-dimethylbutane and 3-nitro-2,2-dimethylpentane, with tin and hydrochloric acid, yielded amines, but that the corresponding isonitro compounds (as the alkali salts) added to stannous chloride and hydrochloric acid gave rise to ketones, ketoximes being formed as intermediate products. These reactions are represented by the following example:



$$(CH_3)_3CCH(NO_2)CH_3 \xrightarrow{(Sn+HCl)} (CH_3)_3CCH(NH_2)CH_3$$

$$\downarrow (KOH)$$

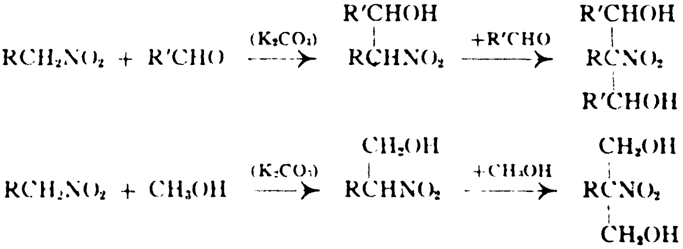
$$(CH_3)_3C\underset{\underset{NO_2K}{\|}}{C}CH_3 \xrightarrow{(SnCl_2+HCl)} (CH_3)_3C\underset{\underset{NOH}{\|}}{C}CH_3$$

$$(CH_3)_3C\underset{\underset{NOH}{\|}}{C}CH_3 + \underset{H}{\overset{H}{O}}\;\underset{H}{\overset{H}{O}} \xrightarrow{(hydrolysis)} \left[(CH_3)_3C\underset{OH\;\;OH}{C}CH_3\right] + H_2NOH$$

$$\xrightarrow{(-H_2O)} (CH_3)_3C\underset{\underset{O}{\|}}{C}CH_3$$

Amines and ketones result from the reduction of the nitro derivatives of the cycloparaffins. Thus, Markownikow[35] reported that nitrocyclohexane is transformed by zinc and glacial acetic acid into cyclohexanone but when the reduction was carried out with tin and hydrochloric acid cyclohexylamine was obtained. Nametkin[36] prepared the corresponding amine from 1-nitro-1-methylcyclohexane and tin and hydrochloric acid. On the other hand, when 3-nitro-1-methylcyclohexane was reduced under similar conditions 3-amino-1-methylcyclohexane and 1-methylcyclohexanone-3 resulted.

Other reactions of primary and secondary nitro compounds are their condensations with aldehydes (aliphatic,[37] aromatic,[38] and chloro-,[39]) and with methyl alcohol.[40] These condensations may be illustrated by the following typical courses of reaction:



$$RCH_2NO_2 + R'CHO \xrightarrow{(K_2CO_3)} R\overset{\overset{R'CHOH}{|}}{C}HNO_2 \xrightarrow{+R'CHO} R\overset{\overset{R'CHOH}{|}}{\underset{\underset{R'CHOH}{|}}{C}}NO_2$$

$$RCH_2NO_2 + CH_3OH \xrightarrow{(K_2CO_3)} R\overset{\overset{CH_2OH}{|}}{C}HNO_2 \xrightarrow{+CH_3OH} R\overset{\overset{CH_2OH}{|}}{\underset{\underset{CH_2OH}{|}}{C}}NO_2$$

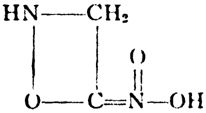
The alkali salts of the nitroparaffins react with halogens,[41] replacing the hydrogen atoms attached to the carbon atom holding the nitro group. By chlorination with hypochlorous acid, nitromethane yields chloropicrin.[42] Primary nitro compounds, when heated with concentrated hydrochloric acid at 150°C. or with phosphoric acid at 100°C., yield the corresponding carboxylic acids.[43] This reaction is shown below:

$$RCH_2NO_2 + HCl + H_2O \longrightarrow RCOOH + HONH_2 \cdot HCl$$

On the other hand, secondary nitropropane[44] is totally decomposed when heated with concentrated hydrochloric acid at 100°C. Fuming sulphuric acid decomposes nitromethane[45] to give carbon monoxide and hydroxylamine but acts on nitroethane[46] to give symmetrical ethane disulphonic acid. Concentrated ammonium hydroxide acts on nitromethane, below 10°C., to give the ammonium salt of methazonic acid.[47] The alkali metal hydroxides act much more vigorously and the reaction is accompanied by considerable decomposition. To methazonic acid has been attributed the structure shown below:



An interesting reaction involving tetranitromethane consists of the introduction of nitro groups into the aromatic nucleus[48] in the presence of pyridine. For example, *m*-nitro-N-dimethyl-*p*-toluidine is formed from N-dimethyl-*p*-toluidine by this treatment. This was the first method used for nitration of the aromatic compounds in an acid-free medium. Reactions of nitroparaffins with diketones,[49] diazo compounds,[50] alkylmagnesium iodides[51] and carbon disulphide[52] have been reported. Taylor and Vesselovsky,[53] in studying the thermal decomposition of nitromethane, found that the main reaction consisted of a unimolecular splitting into nitrosomethane and oxygen. Rice and Rodowskas[54] studied the thermal decomposition of ethyl nitrite, on the other hand, by heating the compound in a furnace under low pressure, and passing the resulting gases over metallic mirrors. Thus, the gases of decomposition were passed over a mirror of tellurium, in several instances. When pure ethyl nitrite was decomposed, the exhaust gases did not attack the mirror. On the other hand, when an inert diluent gas was added, the mirrors were rapidly removed, even when the furnace temperature was no higher than 425°C. The tellurium was found to have been taken up by free methyl radicals, yielding dimethylditelluride, when 1 per cent ethyl nitrite was carried in carbon dioxide.

The investigators believe the reactions involved proceed as follows:

$$(1) \qquad CH_3CH_2ONO \longrightarrow NO + CH_3CH_2O—$$

yielding the free radicle $CH_3CH_2O—$ and the stable molecule NO. This primary decomposition then is followed by:

$$(2) \qquad CH_3CH_2O- \longrightarrow HCHO + CH_3—$$
$$(3) \qquad CH_3- + CH_3CH_2ONO \longrightarrow CH_4 + CH_3CH(ONO)—$$
$$(4) \qquad CH_3CH(ONO)- \longrightarrow NO + CH_3CHO$$

The fact that pure ethyl nitrite did not remove the metallic mirrors was accounted for on this basis by the presumption that reactions (1) and (2) occur in the furnace, and are immediately followed by reactions (3) and (4), thus destroying the free methyl groups before the mirrors were reached. Diluting the ethyl nitrite, then, would reduce the rate of reaction (3), the only bi-molecular reaction of the series, and permit the methyl groups to exist until the mirror was reached. Since the experiment with the tellurium mirror yielded pure dimethylditelluride, it seems probable that only the methyl free-radicals escaped the furnace.

Hass and co-workers,[55] reporting on the toxicity of a sample of nitrated propane (containing also nitromethane and nitroethane in addition to the two nitropropanes), state that its vapors are less toxic than the vapors of benzene, aniline, carbon disulphide, carbon tetrachloride or nitrobenzene.

NITRO COMPOUNDS OF PETROLEUM AND THEIR APPLICATIONS

The increasing use of the Diesel engine has been accompanied by the desire to produce lower-igniting and faster-burning fuels. Although this can be influenced to a considerable extent by selecting fuels of the desired composition, nevertheless extraneous substances have also been added which often cause marked changes in the ignition characteristics of a fuel. Such substances are usually explosive or easily ignitable at relatively low (engine) temperatures. They are generally employed in concentrations of less than 5 per cent in most fuels, and, by means of their explosions or low-temperature ignitions, are able to more completely disperse the injected fuel spray and furnish additional heat which aids in the combustion of the fuel charge. These substances are often referred to as ignition-temperature depressants, or accelerators, or promoters, and impart better ignition qualities to fuels. They are also said to suppress detonation and to decrease delay in inflammation.[56]

The substances which have been used or suggested as ignition promoters include the low molecular weight aliphatic nitro compounds and alkyl nitrites,[57] the alkyl nitrates[58] and the latter mixed with organic peroxides.[59]

Salzberg and Peterson[60] have suggested the use of compounds of the type RR′NN:O, in which R and R′ are alkyl radicals. Thus dibutyl- or di-methyl-nitrosoamine may be used. Besides being used in hydrocarbon fuels, the alkyl nitrates have been added to alcohol fuels,[61] in amounts less than 1 per cent, to improve their burning properties. Griffith and Hill[62] have suggested substances which contain halogen atoms and nitrate groups on adjacent carbon atoms, the nitrate of 9,10-bromohydroxystearic acid being an example.

Some investigators, however, have subjected fuels to nitrating treatments instead of adding extraneous substances to promote ignition. Wingett[63] distilled a fuel, under a pressure of 300 pounds per square inch, in the presence of a small quantity of a mixture of sulphuric and nitric acids. The resulting material was said to be more sensitive to low temperature ignition than before nitration. Grevel[64] treated a gas oil (boiling range 270-360°C., sp. gr. 0.80-0.87) with nitric acid (expediently with fuming nitric acid) and, after the conclusion of gas evolution, neutralized the unused acid with sodium bicarbonate. This oil, either alone or mixed with other petroleum fractions, was suggested as a motor fuel, presumably for motors equipped with spark or similar ignition means and hence not relying on compression to cause ignition. By distillation (with steam or under reduced pressure) decolorization of the nitrated oil was accomplished.

Winand[65] describes a fuel designed especially for submarine engines, which must operate without direct access to the atmosphere. This fuel consists of a mixture of tetranitroethane and mono-, di-, or trinitrobenzol, without the addition of hydrocarbon material. Nitromethane has been employed for the removal of carbon deposits from internal combustion engines.[66] A mixture consisting of nitromethane, benzol and ethyl alcohol is injected into the cylinders which have been previously heated to 150°F. After remaining for 2 hours the engine is started and the carbon blown out the exhaust. Hass and co-workers[67] investigated the possibility of using the nitropropanes and nitrobutanes as lacquer solvents. They found that, when dissolved in an alcohol such as 1-butanol, these nitro compounds possessed dilution ratios equal or superior to those of the ester solvents (butyl and amyl acetates) and that lacquers containing these compounds exhibited good blush resistance. They further report that tests indicate the nitroparaffins possess possible value in the solvent refining of lubricating oils. Fitch[68] has described the production of a resinous substance from olefin material and sulphur dioxide which is soluble in nitromethane.[69] The solution prepared in this way is said to contain a high percentage of solids, and to possess a high viscosity.

Drinberg and associates[70] produced varnish resins by nitrating paraffin oil,

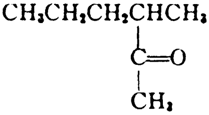
petrolatum, and gas oil with 30°Bé nitric acid, both alone and mixed with 73°Bé sulphuric acid at temperatures of 120°, 130° and 200°C. Such resins were soluble in acetone, amyl acetate, benzene and chloroform, and yielded transparent films on evaporation of their solutions. A brownish resin was obtained from the unsaturated compounds of petroleum and fuming nitric acid. In preparing tar emulsions for use in paving compositions, Daimler[71] used "humic acids" as emulsifying agents. These acids were made by the nitration of coal or pitches and were soluble in alkalies, giving brown solutions. Nitrated petroleum fractions have also been used as dyes, plasticizers and as intermediates in the production of motor fuels.[72]

APPLICATIONS OF FRIEDEL-CRAFTS REACTION TO PARAFFIN AND CYCLOPARAFFIN HYDROCARBONS

Hopff[73] obtained a ketone by the action of acetyl chloride on pentane in the presence of aluminum chloride to which he assigned the structure corresponding to 2-acetylpentane,



$$CH_3CH_2CH_2\underset{\substack{|\\ C=O\\ |\\ CH_3}}{C}HCH_3$$

Later, however, Nenitzescu and Chicos[74] showed, by oxidizing this substance to the corresponding acid, that it was actually 2-acetyl-3-methylbutane. Hence, they postulated the following mechanism:

$$n\text{-}C_5H_{12} \xrightarrow{(AlCl_3)} (CH_3)_2CHCH_2CH_3 \xrightarrow{-H_2} (CH_3)_2C{=}CHCH_3$$

$$\xrightarrow{+CH_3COCl} (CH_3)_2C(Cl)CH(CH_3CO)CH_3 \xrightarrow{+H_2} (CH_3)_2CHCH(CH_3CO)CH_3$$

Similarly, the ketone $(CH_3)_2CHCH(CH_3CO)CH_2CH_3$ was obtained from *n*-hexane. On the other hand, Zelinskii and Leder-Packendorff[75] treated a naphtha benzine, corresponding to the formula C_6H_{14}, with acetyl chloride and aluminum chloride and obtained a 22.5 per cent yield of a ketone mixture which they showed consisted of 1-methyl-2-acetylcyclopentane and 1-methyl-3-acetylcyclopentane. In this work they proved also that 2-methylpentane was not the origin of the ketones formed since it failed to react with acetyl chloride in the presence of aluminum chloride.

Carbon monoxide may be condensed with the paraffins in the presence of aluminum chloride, but whereas the aromatic hydrocarbons condense with carbon monoxide to yield aldehydes, the paraffins in this reaction yield ketones. A study of this reaction led Hopff and Nenitzescu[76] to suggest that the reaction between *n*-butane and carbon monoxide proceeds as follows:

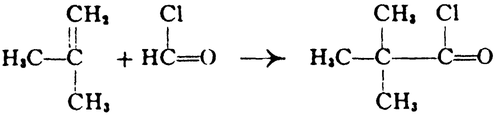
(rearrangement giving mixture of butanes)

$C_4H_{10} \longrightarrow C_4H_8 + H_2$ (mixed butanes dehydrogenated)

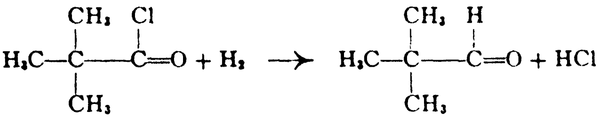
$$CO + HCl \xrightarrow{(AlCl_3)} \left[HCOCl\right]$$

Carbon monoxide (as formyl chloride) adds to the unsaturated compounds to produce from isobutene, trimethylacetyl chloride:



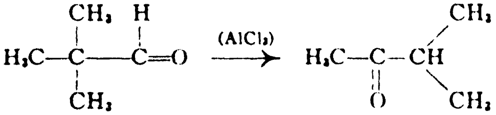
$$H_3C{-}\begin{array}{c}CH_2\\ \|\\ C\\ |\\ CH_3\end{array} + H\begin{array}{c}Cl\\ |\\ C\end{array}{=}O \longrightarrow H_3C{-}\begin{array}{c}CH_3\\ |\\ C\\ |\\ CH_3\end{array}{-}\begin{array}{c}Cl\\ |\\ C\end{array}{=}O$$

This product is reduced by hydrogen (arising from the dehydrogenation) to trimethylacetaldehyde:

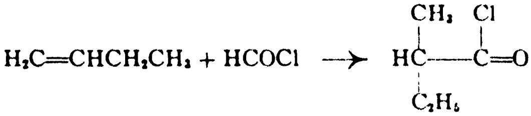


$$H_3C{-}\begin{array}{c}CH_3\\ |\\ C\\ |\\ CH_3\end{array}{-}\begin{array}{c}Cl\\ |\\ C\end{array}{=}O + H_2 \longrightarrow H_3C{-}\begin{array}{c}CH_3\\ |\\ C\\ |\\ CH_3\end{array}{-}\begin{array}{c}H\\ |\\ C\end{array}{=}O + HCl$$

Under the influence of aluminum chloride, rearrangement takes place yielding methylisopropylketone:

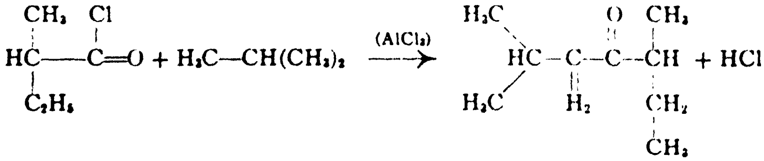


while from *n*-butene and formyl chloride, methylethylacetyl chloride is formed:



$$H_2C{=}CHCH_2CH_3 + HCOCl \longrightarrow H\begin{array}{c}CH_3\\ |\\ C\\ |\\ C_2H_5\end{array}{-}\begin{array}{c}Cl\\ |\\ C\end{array}{=}O$$

This in turn reacts with unchanged isobutane to yield isobutyl-*sec*-butyl ketone:



By interaction of the various products present in the reaction mixture, there arise, in addition to the principal product of the interaction of carbon monoxide and *n*-butane, isobutyl-*sec*-butyl ketone, a complex mixture of methylethylacetic acid, trimethylacetic acid, and *ter*-butyl-isopropyl ketone.

Cyclohexane, in the presence of aluminum chloride, undergoes a primary isomerization to methylcyclopentane which then loses hydrogen and adds acetyl chloride to form a chloroketone.[77] The latter is simultaneously hydrogenated to give

---

[77] C. D. Nenitzescu and G. G. Vantu, *Bull. soc. chim.*, 1935, (5) 2, 2209; *Chem. Abs.*, 1936, 30, 1749.

1-methyl-2-acetylcyclopentane. This isomerization of cyclohexane to methylcyclopentane, according to Nenitzescu and Cantuniari,[78] is not due, however, to the smaller strain of the cyclopentane ring because the strain-free cyclohexane ring appears to be the more stable. No acetylcyclohexane is formed in this reaction. Cyclohexene,[79] on the other hand, gives acetylcyclohexane (methyl cyclohexyl ketone) when treated with acetyl chloride and aluminum chloride in carbon disulphide at −20°C.

Paraffin hydrocarbons have also been shown to react, in the presence of aluminum chloride, with phthalic anhydride to form keto-acids, with ethylene oxide to produce alcohols, and with phosgene and hydrogen to give aldehydes and ketones.[80]

OTHER REACTIONS OF THE PARAFFINS AND CYCLOPARAFFINS

Looker, Kester, Hass and Friend[81] studied the action of nitrosyl chloride (NOCl) on the paraffin hydrocarbons, both in the presence and in the absence of light, and obtained a number of products. The reactions were carried out in the liquid and also in the gaseous phases, and at elevated temperatures and pressures. Since not only nitrosyl chloride but also the products of reaction were very corrosive, the apparatus used was lined with tantalum. Both gaseous and liquid paraffins were suitable as the hydrocarbon materials. In the case of the action of nitrosyl chloride on butane three types of reactions occurred: (1) chlorination, giving mono- and polychlorides with the latter predominating; (2) oxidation, giving fatty acids, including butyric, propionic, acetic and formic acids; and (3) nitrosation, which resulted in the formation of oximes. Nitrosyl chloride mixed with butane produces a slow evolution of gas which finally results in 2 layers, the lower one being miscible, and the upper one immiscible, with water. After the reaction is complete, as indicated by the disappearance of the reddish color (due to unreacted nitrosyl chloride), the mixture is refluxed with the strong hydrochloric acid formed during the reaction so as to hydrolyze the oximes to aldehydes and ketones, and the nitriles to fatty acids. Following hydrolysis, the water-miscible layer is fractionally distilled to give methyl ethyl ketone, acetic acid, propionic acid and butyric acid. A residue composed of ammonium chloride and hydroxylamine hydrochloride remains. The water-immiscible layer is fractionally distilled to give 1-chlorobutane, 2-chlorobutane, 1,1-dichlorobutane, 2,-2-dichlorobutane and other polychlorobutanes. Certain lachrimatory substances are also formed which are thought to be chlorinated ketones.

That light has a strong influence on the course of the reaction between nitrosyl chloride and paraffins has been substantiated by the work of Mitchell and Carson[82] on the color changes ensuing during the reaction between *n*-hexane and nitrosyl chloride. In bright sunlight, the two compounds react to yield a brown oil, which, on steam distillation, yields about equal proportions of methyl-*n*-butyl ketone and methyl-*n*-propyl ketone. When the reaction was carried out in the absence of bright sunlight, a blue color developed slowly, then gradually disappeared, but very little of the oil as from the first experiment was obtained. An absorption-spectrum study of this reaction mixture showed that there were very powerful absorption bands in the violet and ultraviolet, and also bands located in the blue and orange (headed at 4780 Å and 6000 Å respectively). On removing the hydrogen chloride and nitrosyl chloride from one of the blue solutions (by blowing nitrogen through it) it was found that a strong absorption band existed in the red, headed at about 6600 Å. The reaction was then carried on in tubes immersed in cylinders of copper sulphate solution, which served as filters to remove the red rays from light passing through them, and the apparatus exposed to sunlight. Under these conditions, the reaction was arrested at the blue stage, and little oil was formed. When the evolution of hydrogen chloride ceased, the solutions were again saturated with nitrosyl chloride and exposed. This operation was repeated three successive times, and the resulting blue solutions washed with dilute sodium bicarbonate solution, dried, and fractionated under reduced pressure. The blue liquid concentrated in this way, was found to constitute only a few cubic centimeters in each liter of hexane reacted. Analytical data indicated that this liquid, which was quite stable when kept in the dark, consisted of 2,2-chloronitrosohexane and 3,3-chloronitrosohexane.

Lelgemann[83] produced a gasoline substitute from high boiling paraffin material by reacting the latter with nitrosyl chloride at temperatures between 120° and 370°C. in the presence of iron and aluminum chlorides. About 4 to 5 ounces of nitrosyl chloride and 5 to 12 pounds of a mixture of equal parts of the metallic chlorides were used with each 100 pounds of charging stock. The hydrocarbon charge was heated to the temperature of incipient cracking and the nitrosyl chloride introduced at that point.

Rice[84] prepared lead alkyls from paraffins by heating the latter to 500-1000°C. at sub-atmospheric pressures and passing the products over finely divided lead, after which they were rapidly cooled to −80°C. and finally to −190°C. to separate the lead alkyls thus formed. Heptane, for example, gave mainly the methyl and ethyl derivatives when treated in this manner. Nenitzescu and Isacescu[85] investigated the behavior of cyclohexane toward inorganic halides in the presence of aluminum chloride at 65-70°C. Arsenic trichloride, silicon tetrachloride, stannic chloride, sulphur monochloride, thionyl chloride and sulphuryl chloride all converted cyclohexane into bicyclohexyl. Phosphorus trichloride gave unsaturated compounds, whereas mercuric chloride, silver chloride, chromyl chloride and phosphorus oxychloride did not react. Candea and Murgulescu[86] studied the action of metallic halides on methane at much higher temperatures. At 900°C. a 90 per cent yield of hydrochloric acid was obtained from calcium chloride and methane, while at 700° and 1000° C. the yield was 60 per cent. Also, by careful regulation of the conditions, they obtained 60 per cent yields of hydrochloric acid from sodium chloride and methane. Reactions of the saturated hydrocarbons with sulphur, sulphur monochloride, antimony chloride ($SbCl_5$), chlorosulphonic acid and chromyl chloride have also been reported.[87]

Chapter 48

Naphthenic Acids

Oxygen-containing compounds comprise only a small fraction of the constituents of mineral oils and are reported to be of two types, namely, phenolic bodies, such as cresols, xylenols, or di- and triethylphenol, and naphthenic acids.[1] The latter, present in the larger proportion, are the carboxylic derivatives of cycloparaffin hydrocarbons and have found technical applications, particularly in the form of their alkali and heavy-metal salts. Although naphthenic acids occur to some extent in practically all crude petroleums, or their distillates, the chief sources are Russian, Rumanian and, to a lesser degree, Polish oils, the German and American crudes yielding comparatively small quantities. Schmitz[1a] states that the acidity of certain crude oils in the region of Apsheron (Russia) is:

	Acidity, %[a]
Balakhanui light oil	0.08-0.16
Balakhanui heavy oil	0.20
Sabountschy	0.10-0.20
Bibi-Eybat	0.07-0.16
Ramany	0.08-0.18

[a] Analyses made in 1933 and 1934.

The content of naphthenic acids is frequently not greater than 2 per cent and is often less than 0.1 per cent, but even on the basis of 0.1 per cent the potential world-annual production is estimated at 200,000,000 kg. or approximately 50,000 tons.

The proportions of naphthenic acids in various fractions of a Balakhanui lubricating oil distillate and a heavy Balakhanui crude oil, as reported by Blagovidov and Terteryan,[2] are indicated in Table 205.

TABLE 205.—*Proportions of Naphthenic Acids in Balakhanui Oil.*

	% Naphthenic Acids	
Fraction	Lubricating Distillate	Heavy Crude
Kerosene	0.83	0.69
Light gas oil	1.54	1.60
Heavy gas oil	1.65	2.48
Spindle oil	1.57	2.98
Machine oil	1.16	2.68
Cylinder oil	0.82	1.90

Gas oils from Texas and California petroleums are reported to contain 0.35-0.36 per cent acids, and some Louisiana and Gulf Coast crudes as high as 0.67-0.70 per cent.[3] According to Goldberg and Ter-Akopova,[4] determination of acidic constituents should be made by extraction with alcoholic sodium or potassium hydroxide as results obtained with aqueous solutions of alkali are likely to be unreliable because of the formation of emulsions.

Examination of some commercial naphthenic acids from the alkali wash of a West Texas (U.S.A.) pressure distillate was made by Williams and Richter.[5] These investigators found that the acidic constituents consisted for the most part of phenolic compounds, phenol, *o*-, *m*-, and *p*-cresol, 1,3,5-xylenol, and 1,4,2-xylenol. Some ethyl mercaptan was also present. In addition, the following aliphatic acids were isolated; isovaleric, *n*-heptylic, *n*-octylic, and *n*-nonylic. These results seemed to indicate that cyclic carboxylic acids are not present exclusively as many of the earlier workers believed. A study of the mixed acids from a Texas oil was made by Cosciug,[6] who attempted to separate them according to the method of v. Braun and Wittmeyer.[7] Only a very small quantity of one acid, having the formula $C_8H_{14}O_2$ and boiling at 138-142°C. (12 mm.), was secured. The major portion of the acidic bodies, however, appeared to be derivatives of the isomeric hydrocarbons whose constitutions corresponded to $C_{10}H_{18}$.

Although the formation of naphthenic acids in petroleum distillates has been attributed largely to oxidation (by air-blowing) during the alkaline wash of refinery operations, nevertheless some results obtained by v. Braun and Wittmeyer[8] show that these acids pre-exist in the crude oil. A fraction (boiling 180-260°C.) was extracted with liquid sulphur dioxide and the soluble and insoluble portions separated and subjected to an alkaline wash. If the acids were due only to oxidation during this latter operation, then different products should be obtained from the two portions. v. Braun and Wittmeyer found, however, that three times as great a quantity of acids were extracted from the sulphur dioxide-soluble portion as from the other. Even though it was impossible to isolate individual acids, nevertheless comparisons of mixtures of the same boiling range and of their degradation products by the amine-olefin or the progressive degradation method[9] indicated their similarity in properties and constitution. These investigators concluded, therefore, that naphthenic acids were present in the crude distillate prior to oxidation. Attempts to separate the acids into closely related substances by extraction with liquid sulphur dioxide at —10° to —20°C. were not successful.

EXTRACTION OF NAPHTHENIC ACIDS FROM PETROLEUM

Extraction of crude petroleum oils or distillates with alkali usually affords the largest yields of naphthenic acids. Loss of acids may result from the partial refining of distillates or still bottoms, destruction during distillation, unsatisfactory treating procedures, or partial transfer to acid sludge when sulphuric acid is employed as the refining agent.[10] Methods for the recovery of naphthenic acids appear to be of two general types:[11] (1) treatment of the oil with aqueous alkali at elevated temperatures, acidifying the solution, extracting with a low-boiling distillate, and separating acids and distillate by fractional distillation. (2) The oil is distilled in the presence of an alkali, for example, calcium or sodium oxide,[12] and the resulting soaps freed from hydrocarbons by extraction with 80 per cent alcohol, the soaps being soluble in this solvent. Further purification may be effected by aeration of the acids in the presence of cobalt naphthenate.

Washing crude Baku lubricating oil distillates at 60-70°C. with 4 per cent aqueous sodium hydroxide is reported to effect as high as 96.7 per cent neutralization.[13] The alkali sludge so obtained was black in color and contained about 36.8 per cent unsaponifiable material. The treated oil, however, yielded a higher proportion of ash than the untreated. Crude oils having 0.9 to 1.2 per cent petroleum acids can be washed with alkali in like manner, though the addition of 1 per cent of kerosene naphthenic acids may be required to break the emulsions which are formed. Also, it has been pointed out that the removal of naphthenic acids from a residual oil stock and the separation of the latter into distillate fractions may be accomplished in a one-stage operation.[14] A concentrated aqueous solution of sodium hydroxide is incorporated in the oil and the mixture is conducted through a heating coil at about 400°C. In order to maintain the substances in the liquid phase the heating is effected at high pressures. The heated mixture is then led rapidly into the center of a fractionating column, the latter being kept under a high vacuum. The oil which remains unvaporized flows to the lower portion of the fractionating column and is distilled by further heating. Vaporized oil in the center of the column is fractionated to condense a lubricant cut which may be removed as a side stream. Tarry matter, naphthenic acids and caustic soda are removed at the bottom of the column. Alkali sludge from crude oil often contained 50-60 per cent of oil or unsaponifiable matter. Analysis of the organic portion of such sludge (from Bibi-Eibat crude oil) indicated its composition to be 0.23 per cent asphaltogenic acids, 63.52 per cent naphthenic acids, 0.96 per cent asphaltenes, 4.07 per cent resins, and 31.16 per cent oil. The removal of unsaponifiable matter from alkaline sludge is said to be effected by extracting the sludge with a gasoline boiling at 325°C. (end point).[15] Countercurrent operation is said to result in smaller loss of oil and higher yields of acids are secured if the alkali wash precedes refining with sulphuric acid. The use of 10 per cent aqueous calcium chloride for breaking oil and alkali emulsions is suggested by Robinson.[16]

The following procedure is recommended by Gelbke:[17] Waste alkali (from refining mineral oils) is dehydrated and lixiviated with dry acetone and the extract is cooled and allowed to stand until clear. Afterwards the solvent is removed from the clear solution by evaporation.

Removal of naphthenic acids and phenols may be accomplished by bringing a mixture of steam and oil vapors in contact with a hot aqueous solution of sodium hydroxide.[18] The temperature and concentration of the latter are such that an appreciable quantity of steam is neither evolved nor absorbed during the extraction step. The apparatus consists of a steel shell in which are placed trays. The latter contain vapor jets covered by bells to insure an adequate time of contact between the oil vapors and caustic soda solution. In the procedure gaseous oil and water are bubbled through the caustic soda solution to extract the naphthenic acids

which may be drawn off at intervals. In place of the aqueous alkaline solution a suspension of soda-lime in a mixture of naphthenic soaps and oils has been proposed.[10] This extraction medium may be regenerated by the addition of caustic soda. Another procedure comprises conducting the oil vapors through a body of molten, substantially anhydrous alkali.[20] Thus, a mixture of steam and oil is heated to 750°F. in a pipe still (Fig. 269) and conducted to a flash drum, where the tarry constituents are removed. The vapor portion containing the naphthenic acids is then led to a bubble tower containing alkali plates and entrainment plates. Caustic soda is introduced at the top of the alkali plates to remove naphthenic acids and at the same time gas oil is admitted at the upper end of the bubble tower to maintain reflux. Campbell[21] suggests elimination of acidic constituents by scrubbing straight-run distillates with 15 per cent sodium carbonate solution. Phenols may be taken out subsequently by employing 10-20 per cent sodium hydroxide solution.

[20] F. M. Rogers, U. S. P. 2,007,146, July 2, 1935, to Standard Oil Co. of Indiana; *Chem. Abs.*, 1935, **29**, 5645; *J. Inst. Pet. Tech.*, 1935, **21**, 383A; *Brit. Chem. Abs.* **B**, 1936, 730.

In another process, petroleum fractions containing naphthenic acids and phenols are extracted with liquid sulphur dioxide.[22] The extract is then admixed with sodium carbonate to form naphthenates and phenolates. Sulphuric acid is incorporated in an amount sufficient to acidify the mixture. The latter is neutralized with sodium carbonate. In this manner sodium naphthenate is said to be formed, while the phenols are unaffected. These substances may then be separated by fractional distillation.

Several methods have been described for working up the oily still bottoms obtained on the distillation of lubricating oils, or other petroleum fractions, from alkalies. In one of these, the bottoms are heated with water under pressure and the mixture then cooled under the same condition. In this manner boiling of the water is prevented and consequently the formation of emulsions. The hydrocarbon and aqueous soap layers are withdrawn separately.[23] Recovery of the acids may be accomplished by acidifying the soap solution with a mineral acid, adding xylene and distilling to remove water, and extracting the residue with ethyl alcohol.[24] In other instances the water-free alkaline still bottoms are treated with concentrated sulphuric acid to liberate naphthenic acids and these extracted with a solvent.[25] Dilute acid (3-5 per cent) has been recommended instead of concentrated for the decomposition of alkaline bottoms and after separation of the solution of naphthenic acids in oil (adding gas oil if necessary to effect demulsification) the latter may be subjected to cracking to furnish a motor fuel.[26] This process is illustrated diagrammatically in Fig. 270. It has been pointed out that alkaline sludge may be treated with calcium hydroxide and gas oil to effect the removal of naphthenic acids.[27] The latter are converted to copper naphthenates which are said to dissolve in the gas oil. In this manner two layers are said to be formed; the lower an aqueous solution of sodium hydroxide, the upper the naphthenic soaps in gas oil. The soaps may then be converted into free acids by incorporating sulphuric acid in the upper layer. Also, it has been recommended that alkaline sludge be emulsified with water in the presence of a light oil which serves as a diluent.[28] The emulsion is then acidified with sulphuric acid to free the naphthenic acids, which separate together with the diluent oil. The latter mixture is removed, the diluent separated, and the naphthenic acids subjected to vacuum distillation. A flow diagram of this process is indicated in Fig. 271.

Wunsch[29] prepared naphthenates in the following manner. Alkali sludge was dispersed in water and then thinned with an organic solvent such as benzene, amyl alcohol or carbon tetrachloride. Demulsification of the mixture was effected by heating to 90-100°C. and adding an electrolyte, e.g., sodium chloride, after which the mineral oil layer was removed. Although alkali sludge may be dissolved in water and entrained hydrocarbons extracted therefrom with a solvent oil, nevertheless separation is not complete and some alkali naphthenates remain suspended in the solvent oil. A countercurrent system involving extraction of the oil suspension with water to remove alkali naphthenates and extraction of the aqueous solution with solvent oil to eliminate hydrocarbons is described by Hendrey.[30]

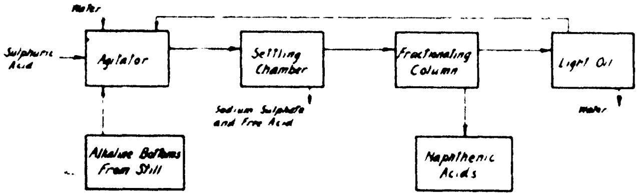

FIG. 271.—Flow Scheme for Recovery and Refining of Naphthenic Acids from Petroleum Oils. (R. F. Nelson and L. Zapf)

Also it has been reported that alkaline sludge may be combined with hydrogen fluoride to effect the separation of naphthenic acids.[31] The sludge is incorporated with calcium fluoride and sulphuric acid. The latter substances produce hydrogen fluoride

$$CaF_2 + H_2SO_4 \longrightarrow CaSO_4 + 2HF$$

which then interacts with the sodium naphthenates to free the naphthenic acids,

$$RCOONa + HF \longrightarrow RCOOH + NaF$$

where *R* represents a cycloparaffin with an alkyl side chain. Sodium fluoride may be transformed into calcium fluoride by calcium hydroxide. In this manner a recovery of 90 per cent of the caustic soda and 99 per cent of the naphthenic acids is said to be secured.

PURIFICATION OF CRUDE NAPHTHENIC ACIDS

The crude acids recovered by acidifying alkali sludge from refining of mineral oils are for the most part dark-colored, disagreeable smelling liquids boiling between 120°C. (at 12 mm.) and 300°C. (at 0.1 mm.).[32] The impurities are primarily hydrocarbons and some phenolic bodies. Methods which have been proposed for the purification of these acids include fractional distillation, reaction with basic compounds, such as aniline, followed by separation of the salt formed, and extraction of naphthenic soaps (either in the dry state or dissolved in a solvent.)[33] Goldberg and Shaverdova,[34] however, report that acids of high molecular weights easily decompose when subjected to distillation.

Deodorization may be accomplished by treating crude acids with oxidizing or reducing agents, or by heating their soap solutions to high temperatures under pressure. Bagirov[35] suggested heating a mixture of alkali sludge (soaps) and kerosene with steam and simultaneously agitating with air. Afterwards the mixture is allowed to settle and the lower layer, consisting of soap and kerosene, is withdrawn. The kerosene can be separated by distillation. Rabinovich and Osenova[36] described a method in which bleaching and deodorization of naphthenic acids is effected. The latter are dissolved in gasoline (50 per cent solution) and treated with small proportions of concentrated sulphuric acid. After removal of acid sludge, the gasoline solution is further treated at 50-60°C. with 5-10 per cent of an adsorption agent (gumbrin[36a]), filtered, and washed with an aqueous solution of an electrolyte, such as zinc or calcium chloride. This procedure is said to yield a product which is more homogeneous and stable than the crude acids but possessing somewhat less acidity. The foaming power of the corresponding potassium soaps is also slightly lower than that from unpurified acids.

It has been stated that the removal of color and odor from naphthenic acids may be accomplished by distilling a mixture of crude naphthenic acids to remove any carbonaceous materials.[37] The naphthenic acids are then redistilled in the presence of copper oxide. In another procedure the crude acids are admixed with air and nitrogen dioxide at 245-300°C.[38] The oxidizing agents are employed in an amount 50 times as great as the volume of the liquid naphthenic acids. Also, the acids may be filtered through an adsorbent such as fuller's earth.[39]

Hendrey[39a] recommends treatment with concentrated sulphuric acid followed by distillation under reduced pressure. This type of operation is intended to provide a decolorization of the carboxylic acid.

CONSTITUTION AND CHEMICAL PROPERTIES OF NAPHTHENIC ACIDS

Although the term naphthenic acids has been employed broadly to designate acids found in crude petroleum or its distillates, nevertheless it appears that such acids containing up to 6 carbon atoms per molecule are aliphatic, those possessing 7 to 12 carbon atoms are monocyclic compounds, and those having more than 12 carbon atoms are dicyclic.[40] In some instances the low-molecular weight acids found in distillates are not present in the crude oil, thus indicating that such bodies are the result of pyrogenic decomposition. Furthermore, the main ring system, in the cyclic acids, is a cyclopentane ring and the carboxyl group is predominately on the end of an alkyl side chain attached to the single or a double ring structure.

FIG. 272.
Prof. Julius von Braun of Heidelberg, Germany. His researches have materially extended our knowledge of the chemical constitution of naphthenic acids.

One method of ascertaining whether the carboxyl group is connected to the cyclopentane nucleus through a CH_2 or CH group is that described by von Braun.[41] The naphthenic acid is converted (by ethylamine) to its ethylamide derivative and the latter is chlorinated with phosphorus pentachloride. This resulted in the formation of an imidechloride, $-CH_2C(Cl)=NC_2H_5$ or $>CHC(Cl)=NC_2H_5$, which in turn further reacted (with phosphorus pentachloride) to yield di- or monochlorinated derivatives, respectively,

$$-C(Cl)_2C(Cl)=NC_2H_5 \text{ or } >C(Cl)C(Cl)=NC_2H_5$$

Hydrolysis of the chlorinated imidechlorides gave the corresponding di- or monochloro naphthenic acid. In this manner an acid of the type RCH_2COOH furnished the product $RCCl_2COOH$, and $RCH(CH_3)COOH$ gave rise to $RCCl(CH_3)$-COOH.

The number of chlorine atoms present in 100 molecules of the chlorinated acid was called the chlorine number. This value can be readily calculated by the formula

$$\frac{x}{100 - x} \cdot \frac{M}{35.5} \cdot 100$$

in which x is the percentage of chlorine in the product and M the molecular weight of the acid under investigation. Chlorine numbers of 200 and 100 denote acids consisting wholly of the types $—CH_2COOH$ and $>CHCOOH$, respectively, and intermediate numbers indicate a mixture. Thus, a value of 180 means that the sample contains 80 per cent of acids having the $—CH_2COOH$ group and 20 per cent of acids possessing the other group.

Two methods[42] are available for determining the number of carbon atoms in the chain attaching the carboxyl group to the cyclic nucleus: (1) the amine-olefin and (2) the progressive degradation. In the former, the naphthenic acid is reduced by hydrazoic acid to the corresponding amine, which in turn is converted to an olefin and the latter then oxidized. If an even number of carbon atoms were in the side chain the final product is an acid. An uneven number of carbon atoms gives rise to a ketone. In the second procedure, the acid is reduced to the alcohol from which the corresponding bromide, quarternary ammonium base, and olefin are prepared successively. The last-named derivative is subjected to oxidation. Again the final product is an acid or ketone indicating an even or odd number of carbon atoms, respectively, in the side chain.

The properties of naphthenic acids, in general, correspond to those of saturated aliphatic acids. The alkali salts are water-soluble and hydrolyze to about the same degree as the sodium or potassium soaps or fatty acids. The alkaline-earth and heavy-metal salts are insoluble in water, but soluble in organic solvents such as benzol or benzine. The acids may be converted into acid chlorides and these in turn into such derivatives as esters or amides. Esters of naphthenic acids, particularly those made from methyl alcohol, are well-known.[43] Reduction of the acids, their chlorides, or esters leads to the formation of naphthenic alcohols.[44] Also, it has been stated that naphthenic acids will interact with acetic anhydride to furnish the anhydrides of the naphthenic acids.[45]

APPLICATIONS OF NAPHTHENIC ACIDS

One use suggested for these acids is the breaking of various types of oil emulsions. For example, in the neutralization step following the acid treatment of certain lubricating oil distillates very stable emulsions are formed. The latter may be avoided, however, by the addition of naphthenic acids to the oil.[46] Demulsification of oil and water emulsions may be accomplished by employing a small proportion of a solution containing either 0.25 per cent naphthenic acids and 0.25 per cent sodium chloride or 0.2 per cent acids and 0.2 per cent sodium hydroxide.[47] Incorporation of the acids, or their salts, with low-grade mineral oils is said to increase the viscosity of such oils at ordinary temperatures but not at higher temperatures, e.g., 110-150°C.[48] Improvement in the color stability of gasolines is secured by the introduction of 0.001-0.5 per cent of naphthenic acids and 0.001-0.1 per cent of a red dye of the Sudan type.[49]

---

[42] For a fuller description of these methods see, Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., New York, 1934.

The reduction of ethyl tetramethylene carboxylate is described by N. Ya. Demyanov, *J. Russ. Phys. Chem. Soc.*, 1910, **42**, 837; *Chem. Abs.*, 1911, **5**, 3832; *J.C.S.*, 1910, **98** (1), 838. Other methods for preparing naphthenic alcohols from the corresponding acids are given by Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., New York, 1934.

[45] D. Holde, *Chem. Umschau*, 1923, **30**, 198; *Chem. Abs.*, 1923, **17**, 3615; *J.S.C.I.*, 1923, **42**, 896A.

[46] Z. Nekrasov, *Neft*, 1933, **4** (3 4), 18; *Brit. Chem. Abs.* **B**, 1935, 1032; *Chem. Abs.*, 1935, **29**, 2722.

According to Petrov,[50] artificial asphalts are obtained by heating petroleum acids to temperatures above 180°C. Swerissen[51] proposed adding an acid, e.g., acid sludge, to mineral oil residues containing naphthenic soaps and then subjecting the resulting mixture, containing the decomposition products of the soaps, to an oxidizing treatment to produce an asphalt.

Emulsifying, dispersing or softening agents are reported to be obtained by treating naphthenic acids with a mixture of sulphuric acid and its glycerol esters.[52] The reaction products of glycerol and naphthenic acids have been suggested as wetting and washing materials.[53] Loose, powdered compositions of the latter type can be prepared by incorporating water-soluble naphthenates of polyglycerol with alkali sulphates, such as sodium, ammonium or potassium sulphate.[54] Alkali meta- or pyrophosphates may be added. Naphthenic or sulphonaphthenic acids are said to increase the detersive power of soap solutions, the distilled acids from petroleum being a particularly effective ingredient in detergents.[55] Esters of naphthenic acids,[56] or of halogenated or alkyl substituted acids,[57] and partially etherized di- or polyhydric alcohols have been proposed as plasticizers for cellulose esters.

Insecticidal sprays can be prepared in the following manner.[58] A petroleum distillate (which may range from a light kerosene to a heavy lubricating oil) is emulsified with 5 per cent glyceryl naphthenate and water. A mixture of calcium caseinate (98 per cent) and aluminum sulphate (2 per cent) is dissolved in water and the solution incorporated with the emulsion to act as a spreader. The glyceryl naphthenate is reported to regulate the deposition of oil on plant leaves and to retard or prevent its absorption. Also, naphthenic acids have been suggested as solvents for insecticidal compositions, the latter being prepared from mercaptans and disulphides occurring in petroleum.[59]

According to Teichmann,[59a] esters resulting from the interaction of phenols and naphthenic acids may be dissolved in hydrocarbon oils or incorporated with oil-water emulsions to furnish insecticides and fungicides. On the other hand, Steik[59b] points out that the product obtained on heating the acids and castor oil at 270°C. for 1 to 1.5 hours is a neutral mutual solvent for castor oil and mineral oils.

NAPHTHENIC ACID SOAPS AND THEIR USES

The alkali soaps of naphthenic acids compare favorably with those of fatty acids with respect to foam-producing and emulsifying qualities, degree of hydrolysis, and solubility in water. However, their application as detergent materials has been limited in many instances due to the disagreeable odor associated with them. It has been suggested that high-molecular weight acids be separated by distillation from those of low molecular weights as well as from resinous and asphaltic impurities, and that the soaps be subjected to a salting-out operation.[60] As previously mentioned, however, deodorization of naphthenic acids is often a very difficult task.[61]

Comparisons of the capacity of solutions of sodium soaps of rosin, ricinoleic, oleic and naphthenic acids for carrying suspended particles of manganese dioxide through filter paper were made by Tyutyunnikov and Kas'yanova.[62] This is analogous to the carbon number of soap solutions.[63] Of the soaps tested only sodium oleate effected passage of the dioxide particles through the paper. Measurements of the detergent (oil-removing) power of soap solutions (0.25-1.0 per cent concentration) indicated that naphthenic soaps were lacking in this property.[64] Nevertheless, the detergent action of ordinary (fatty acid) soap was decreased by incorporation of alkali naphthenates. On the other hand, addition of sodium carbonate to naphthenate soaps (alone or mixed with rosin soaps) increased their washing power. Other investigators, however, report that sodium naphthenates exhibit properties somewhat inferior to ordinary soaps but better than rosinates.[65] It has been noted that the presence of sodium carbonate diminished the amount of dye (Fast Yellow) adsorbed from an olein soap solution by carbon, did not affect the quantity removed from naphthenic acid soap, and increased the proportion adsorbed from rosin soap solution.[66] The detergent properties of naphthenic acids are utilized in washing textiles.[67] For example, a cellulose acetate fabric was wetted with naphthenic acids. At the end of a contact period of 2 hours the fabric was treated at 75°C. in a bath of aqueous caustic soda (containing 1 g. of sodium hydroxide per liter). In this manner a portion of the acid was said to be neutralized. The soap thus produced formed an emulsion with the free acid. Additional caustic soda was then incorporated to neutralize the bath and the fabric scoured at 75°C. in a bath containing 0.25 g. of sodium carbonate per liter of solution. The emulsion which formed was stated to contain any dirt in the fabric, so that the dirt was removed in the final scouring operation.

The emulsifying properties[67a] of naphthenic soaps together with their disinfectant[68] and insecticidal value render them useful as substitutes for fatty acid soaps in the preparation of petroleum emulsions for spraying compositions. Such emulsions are said to cause less damage to foliage than lime-sulphur.[69] An insecticide containing both naphthenates and sulphur is described by Berry.[70] Alkali wash liquors (from resin-forming light distillates) are acidified and the oily layer which separates is removed. Elemental sulphur is dissolved in it and then the naphthenic acids contained therein are neutralized with a base such as sodium carbonate.

Substantially anhydrous sodium naphthenate, made from acids having an average molecular weight of 225 and a distillation range of 230-310°C., may serve as a demulsification agent when mixed with a small proportion of free acids.[71] The influence of sodium hydroxide and sodium sulphate upon naphthenic soaps has been studied.[72] It was stated that aqueous solutions of naphthenic soaps, when treated with caustic soda and sodium sulphate, formed oil-in-water and water-in-oil emulsions. If the temperature is low, the formation of a water-in-oil emulsion was said to be favored. Heating of this emulsion causes it to break, the soap being transferred to the water. With oil-in-water emulsions, however, heating to 70-80°C. will not effect a separation, since an increase in the temperature causes the stabilization of this type of emulsion. If the oil-in-water emulsion is cooled without agitation the emulsion is reported to break, the soaps entering the oil phase. An oil-in-water emulsion reported to be applicable as a lubricant in cutting threads in pipes or bolts has been reported.[73] The oil is prepared by heating 15 per cent of sodium naphthenate to 180-300°F. (82-149°C.). A small proportion of rosin (5 per cent) and the same quantity of ethylene glycol is then incorporated.

Hendrey[73a] describes the preparation of a soluble oil by mixing 16 parts of sodium naphthenates, 1 to 5 parts of pine oil and about 2 per cent of water. Kaufman and Puryear[74] recommend a mixture of sodium stearate and sodium naphthenate dispersed in a heavy mineral lubricating oil. A small proportion of alkali (0.32 per cent) and a trace of water may be included.

Among the other uses for which naphthenic soaps have been suggested is the prevention of acid formation during the distillation of acid-treated mineral oil.[74a] A quantity of sodium naphthenate is added to the oil to take up any acid-reacting substance which may be evolved during the distillation. Also, it has been pointed out that naphthenic soap may be incorporated with ethylene glycol to form a fluid which may be employed in hydraulic brake systems.[75]

Other Naphthenic Acid Salts

Of the heavy metal salts, the lead, cobalt and manganese naphthenates (Soligen driers) are probably the best known. They are widely employed as driers in paints and are reported to be more effective than the corresponding linoleates or resinates.[76] Knauss[77] considers that naphthenate driers differ from other types in that after precipitation of the anti-oxygens in the paint vehicle the remainder of the drier stays permanently in solution.

Although naphthenic acids are found in practically all petroleum oils nevertheless careful selection of the stock must be made to secure driers exhibiting the desired degree of solubility.[78] According to Kisselev and Norina,[79] these driers are prepared by adding a 10 per cent solution of the corresponding metallic salt to a 5 per cent solution of sodium naphthenate, the temperature being kept at 60° C. Acid naphthenates are said to be more soluble in oils than the basic or neutral salts both of which exhibit a pronounced tendency to precipitate from solutions in oils. Aqueous solutions containing a mixture of salts, e.g., lead nitrate and manganese chloride, may be employed and precipitation effected at the boiling temperature of the liquid.[80] Another procedure comprises reacting the metallic oxide with the acids in the presence of a liquid which is a solvent for the resulting naphthenate.[80a] Greenfield[81] points out that the acid fractions boiling between 280° and 300°C. are best for the production of lead and manganese salts, and those boiling at 270°C. yield the best cobalt salts. Meidert[82] suggested the addition of 6-10 per cent of a saturated fatty acid (e.g., palmitic acid) to naphthenate driers. Also, it has been pointed out that the salts of naphthenic acid will combine with halogenated olefins to furnish a drying oil.[83]

Copper naphthenate is proposed as a component of priming coats intended as preservatives for wood.[84] Cellulose esters, such as the trilaurate, together with ferric, lead, or copper naphthenate dissolved in an aromatic hydrocarbon as a solvent are reported to be anti-rust paints for iron.[85] Aluminum naphthenate admixed with glyceryl naphthenate or partially esterified glyceryl oleate is added to mineral oil distillates to furnish insecticidal sprays.[86] Electrical insulators may be obtained by immersing fibrous materials, e.g., tape or cords, in molten salts of naphthenic acids.[87]

Ammonium naphthenate is suggested as a coagulant for bituminous emulsions[88] and mixed with ammonium salts of petroleum sulphonic acids, which may be of the oil-soluble type,[89] as a demulsification agent for petroleum emulsions.[90] Butylated naphthalene sulphonic acid may replace the petroleum sulphonic acids.[91] In another method proposed for demulsifying petroleum emulsions, alkaline sludge containing free alkali is incorporated with the oil.[92] An undistilled heavy oil in the lubricating oil range and metallic salts of naphthenic acids are then added at 85-90°C.

Silicon carboxylates, derived from fatty or naphthenic acids, are said to be hydrogenation catalysts.[93] These may be prepared by reacting 1 mole of silicic-acetic anhydride with 4 moles of the carboxylic acid. Copper naphthenate is stated to be effective as a contact agent for the polymerization of butadiene.[94] When the diolefin was heated in the presence of the naphthenic salt, it was said that 45 per cent of the dimer was formed, but that no higher polymers were secured.

Metal salts of naphthenic acids have been used in the preparation of "extreme pressure" lubricants. Thus, a small proportion of aluminum naphthenate was incorporated in a mineral oil together with graphite.[95] The purpose of the naphthenic salt is to maintain the graphite, which is insoluble in oil, in a finely divided state. Also, the naphthenates are said to prevent formation of carbon on lubricated metal surfaces by peptizing the carbon and dispersing it in the oil. Another lubricant consists of a mixture of petroleum oil, sulphur and lead naphthenate.[96] The addition of tin naphthenate to oil intended for internal combustion engines is said to prevent oxidation and to increase the life of the oil.[97]

Metal salts of naphthenic acids, particularly copper naphthenate, have been employed as preservatives. In one instance, fishing nets were impregnated with a mixture of tar and copper naphthenate.[98] It was stated that with this mixture the nets retained 70 per cent of their initial strength after immersion in sea water for a period of 10 months. Also it has been reported that a copper naphthenate may be prepared in the fabric which is to be impregnated. A saturated aqueous solution of copper sulphate was poured into aqueous ammonium hydroxide (containing 25 per cent of the hydroxide) and naphthenic acids incorporated in the solution.[99] The product, which has a dark blue color, is then added to the fabric to be treated. It is stated that the ammonia evaporates, leaving a protective solid colloid which enables the fabric to withstand immersion in water for 6 months without losing its strength.

The corrosive action of crude oil containing sulphur compounds or salts of magnesium and calcium during distillation is said to be minimized to a large extent by the addition of zinc naphthenate to the crude oil.[100] The naphthenic salt was prepared by dissolving 1 volume of alkali sludge in 2 volumes of water at 90°C. and then incorporating zinc chloride in the solution. The resulting zinc naphthenate was removed from the mixture and dissolved in a gas oil heated to 95°C. The naphthenate solution was then incorporated in the crude oil before distillation of the latter.

Naphthenic salts of alkaline earth metals have been suggested as dispersion agents for carbon black to be employed in printing inks, lithographic varnishes or lacquers.[101] The carbon black is placed in an aqueous solution of sodium naphthenate and an alkaline earth salt added. In this manner the alkaline earth naphthenate which forms is said to be precipitated, carrying with it the carbon black in a finely dispersed state. The color, luster and gloss of the latter are said to be improved by the adsorption of magnesium, calcium, barium or strontium naphthenates.[101a] The naphthenates of such metals as zinc, lead, iron, titanium, nickel and copper are said to be efficient wetting agents in aiding the dispersion of pigments in printing ink vehicles.[102]

SULPHONATION OF NAPHTHENIC ACIDS

As a rule, naphthenic acids are soluble in concentrated sulphuric acid (with the evolution of heat) and are thereby sulphonated only to a limited extent. Gurwitsch[102a] states that treatment (of acids from kerosene) with 100 per cent of concentrated sulphuric acid for 1 hour at room temperature effected only 1.8 per cent sulphonation. The derivatives thus formed were readily separated from the unreacted bodies by washing with water. Pyhälä[103] reported that the acids from Russian kerosene distillates (which had not been refined with sulphuric acid) had a neutralization value of 230 and contained 0.1 per cent sulphur. When these were sulphonated the neutralization value rose to 240 and the sulphur content to 3.64 per cent. The disagreeable odor of the acids increased with sulphonation and this, Pyhälä considered, supported his contention that sulphur compounds were the cause of such odor.

According to Lidow,[104] sulphonation can be effected in the following manner: 100 parts of acids are agitated at room temperature for 2 days with 36.3 parts of sulphuric acid (66° Bé.). Afterwards the oily layer is washed with an aqueous solution of sodium sulphate or chloride, water alone furnishing a persistent emulsion. The product is then neutralized with sodium hydroxide solution (18° Bé.) and may be employed as a substitute for Turkey-red oil. Davidsohn,[105] however, failed to obtain sulphonated materials by this method and suggested another procedure. To 100 g. of acids are slowly added 300 g. of fuming sulphuric acid. After several hours the mixture is washed with an aqueous solution of sodium chloride. The resulting dark colored liquid, of disagreeable odor, had an SO_3 content of 7 per cent, and yielded fairly stable emulsions with water.

From the results of comparative dyeing tests Ulzer[106] concluded that sul-

phonated naphthenic acids were not nearly as good as Turkey-red oil from castor oil, particularly as the former yielded a much less fiery red color. On the other hand it has been reported that in para red dyeing sulphonaphthenic acids were more effective in promoting dispersion of the color lake and reducing surface tension of the naphthol solution than castor-oil soap or soluble oil.[107]

Wetting, cleansing and emulsifying agents may be prepared by the action of sulphonating agents, e.g., chlorosulphonic acid, on mixtures of naphthenic acids and aromatic hydrocarbons or their amino, halogenated or hydroxy derivatives.[108] In place of the latter compounds, alcohols, mercaptans, ketones or carboxylic chlorides may be employed. Metallic salts of sulphonaphthenic acids are suggested as sizing materials for rayon yarns[109] and as addition agents for lubricating oils.[109a]

NAPHTHENIC ALCOHOLS

As previously mentioned, these alcohols may be obtained by catalytic reduction of the corresponding acids. A study of such compounds so prepared from (a) petroleum naphthenic acid and (b) from a spindle oil fraction was made by Lederer.[110] Although the alcohols in both instances were mixtures, nevertheless he concluded, from their boiling point curves,[111] that the product (boiling 165-274°C.) from the petroleum acids consisted principally of undeka- and dodeca-naphthenols, while those (boiling 335-375°C.) from the spindle oil were mainly eikosan- and heneikosan-naphthenols. The acetyl number and average molecular weight for the lower-boiling alcohols were 268 and 169, respectively, and these same values for the other material were 162 and 309, respectively. Lederer considered the constitutions of the alcohols were further substantiated by comparison of their physical properties (e.g., specific heat, viscosity, and interfacial tension against water) with those exhibited by 8-hexadecenecarboxylic acid, 9-octadecanol, octadecadiene, cyclohexanol, methyl cyclohexanol, and tetralin. The tendency of these two naphthenol fractions towards autoxidation was greater than that shown by oleyl alcohol or octadecene, but less than that for tetralin and cyclohexanol.

The rates of esterification of some polymethylene alcohols with acetic anhydride were investigated by Menschutkin.[112] His procedure was to dissolve equimolecular quantities of the alcohol and anhydride in benzene, and then heat the solution (in sealed tubes) for 24 hours at 100°C. At the end of this period, the proportion of acetic acid formed, according to the reaction

$$\mathrm{ROH} + (\mathrm{C_2H_3O_2})_2\mathrm{O} \longrightarrow \mathrm{ROOCCH_3} + \mathrm{CH_3COOH}$$

was determined by titration. The esterification constant (C) was calculated using the formula

$$C = \frac{x}{A - x} \cdot \frac{1}{t}$$

in which $A = 100$, x = per cent of ester formed, and t the time in minutes. His results for some pentamethylene alcohols are given in Table 206.

Menschutkin also noted that secondary alcohols from cyclic hydrocarbons were esterified more rapidly than secondary alcohols from aliphatics. This was illus-

Naphthenic alcohols have been suggested as solvents or emulsifiers in the preparation of pastes for carbon papers or ribbons.[113] Chlorination or sulphonation furnishes wetting or dispersing agents.[114] Esters of these alcohols and halogenated non-aromatic acids may be condensed with sodium derivatives of hydroxy compounds,[115] e.g., sodium phenolate, or with tertiary amines,[116] such as pyridine, to furnish products having saponaceous properties. Esters resulting from interaction of naphthenyl alcohols and polycarboxylic acids, anhydrides or chlorides are reported to be effective as plasticizing agents for cellulose esters and ethers.[117]

Chapter 49

Analysis of Natural Gas and Cracking Gas

Around the determination of the proportion of gases in mixtures there has grown up a considerable measure of technology. Exact determinations call for familiarity with the subject resulting from a sufficiently long experience on the part of the operator. Even so, reported gas analyses are frequently of a doubtful nature. For earlier work and data see "The Chemistry of Petroleum Derivatives," 1934 edition.

Natural gas, which is found to some extent in association with crude petroleum, consists essentially of a mixture of homologous hydrocarbons of the paraffin series. In the "dry" gases methane is the predominating constituent, while the "wet" gases[1] contain the higher homologues of methane in substantial amounts.[2] Besides gaseous and readily liquefiable hydrocarbons natural gases contain varying proportions of non-hydrocarbon gases, including nitrogen, carbon dioxide, hydrogen sulphide and helium. Carbon monoxide, hydrogen and unsaturated hydrocarbons are usually absent from natural gases.

Another important type of petroleum gas is that obtained as a by-product in the commercial cracking of higher petroleum fractions for the production of motor fuels and to which the name "cracking gas" or "cracked gas" has been applied. This differs from natural gas in its content of unsaturated hydrocarbons and hydrogen.[3] Quantities of carbon monoxide are also present, particularly when cracking is conducted in the presence of steam or oxygen.

The analysis of these complex mixtures of saturated and unsaturated hydrocarbons presents difficulties not encountered in the analysis of other gaseous fuels, such as coal gas or producer gas. In the latter, methane (associated with a small proportion of ethane) is the main saturated hydrocarbon constituent and ethylene the chief unsaturated component, so that absorption and combustion methods are adequate for a complete quantitative examination. In petroleum gases, however, at least three members of a homologous series occur together, and the precise analytical differentiation presents some difficulties, particularly in the paraffin series.

The ordinary methods of gas analysis may be used with appropriate modifications to analyze petroleum gases, but only in some cases can complete information be obtained. Most of the non-hydrocarbon constituents, including carbon dioxide, hydrogen sulphide, oxygen and carbon monoxide, may be estimated by absorptions in appropriate liquid reagents. Absorption in sulphuric acid of varied concentrations may be employed to show the total unsaturated hydrocarbon content. As the ordinary combustion and explosion procedures of analysis can be applied only to mixtures of two paraffin hydrocarbons, they are generally inadequate in the case of petroleum gases unless used in conjunction with some physical method of segregation. Two physical methods which have been developed involve the partial or complete separation of each component hydrocarbon by fractional condensation and fractional distillation. Analytical methods for the analysis of petroleum gases may thus be divided into absorption procedures, combustion or explosion processes, and physical methods of segregation. In general all three methods are necessary for the complete, quantitative examination of complex gas mixtures.

ANALYSIS BY ABSORPTION

The analysis of natural gas and cracking gas by absorption depends upon the removal of an individual constituent, or a group of components, by treatment with appropriate liquid reagents in a definite order. By measuring the volume of gas remaining after each absorption, the composition of the mixture may be determined. However, the choice of liquids is difficult in some cases, particularly when unsaturated hydrocarbons are present. Some of the reagents employed in gas analysis, such as sulphuric acid, are capable of absorbing several constituents. When a definite order of absorption is employed this difficulty can be avoided to some extent.

FIG. 273.—Apparatus for Study of Solubility of Carbon Dioxide in Salt Solutions. (K. A. Kobe and J. S. Williams)

The apparatus generally used consists of a gas burette or eudiometer enclosed in a water jacket (for temperature control) and containing a liquid levelling device (mercury, water or other liquid) for pressure control.[4] The gas is conducted from the burette into a pipette which holds the absorbent liquid. At the end of a definite period of time varying between 2 and 5 minutes, the gas is withdrawn and its volume remeasured. By successive absorption and measurement the volume of the other constituents, and the percentage composition, may be found. In some cases the change in pressure at constant volume is observed rather than the change in volume.

[4] Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., Inc., New York, 1934. For a review of the progress of the natural and refinery gas industry, see G. A. Burrell, *Ind. Eng. Chem.*, 1934, 26, 143; *Chem. Abs.*, 1934, 28, 1840; *Brit. Chem. Abs.* B, 1934, 227.

In the description of the reagents for the absorption of the constituents of a gas mixture, the order of their use in analysis will be followed, at least in the case of the more common components, carbon dioxide, acetylene, other unsaturated hydrocarbons, and carbon monoxide.

Carbon dioxide is absorbed in a concentrated aqueous solution of potassium hydroxide prepared by dissolving 500 g. of stick potassium hydroxide in 500 cc. of distilled water.[5] According to Walter[6] sodium hydroxide may be employed instead of caustic potash. In this method the gases are conducted through a vertical tube in which they are mixed with a fine spray of caustic soda. The amount of carbon dioxide absorbed is determined by measuring the electrical conductance of the absorbent before and after passage of the gases.

The choice of a confining liquid[7] for gas analysis has received some attention. Kobe and Williams[8] made a study of the solubility of carbon dioxide in a number of aqueous solutions which have been recommended for this purpose. The apparatus consisted of a gas burette containing mercury. Carbon dioxide was collected in this burette and measured. An absorption bulb partly filled with mercury was connected to the burette. (See Fig. 273.) The solution which was being tested was then poured into the absorption bulb, after which the gases were forced into the bulb and the mixture agitated. At the end of 15 minutes the carbon dioxide was withdrawn and its volume remeasured. The results reported for a number of solutions may be seen in Table 208.

The investigators point out that a concentrated solution of calcium chloride dissolves the least carbon dioxide but has a number of disadvantages which render it objectionable as a confining liquid. The solution is rather viscous, it is easily contaminated with impurities, in which case precipitates are formed, and when spilled it does not evaporate and leave crystals but remains as a sticky liquid. Magnesium chloride solution is much less viscous. However, the magnesium compound has been observed to form a precipitate of magnesium hydroxide when it comes in contact with the concentrated caustic potash and soda absorbents. Sodium sulphate is reported to be the most efficient of the compounds studied, since the addition of sulphuric acid to the sulphate does not increase the solubility of the carbon dioxide in the latter. This incorporation of acid is necessary, as a confining solution, it is stated, must not be alkaline.

Acetylene may be determined by absorption in an alkaline solution of potassium mercuric iodide prepared by dissolving 25 g. of mercuric iodide and 30 g. of potassium iodide in 100 cc. of water.[9] A small proportion of potassium hydroxide is added to the reagent just prior to use.

Among the methods suggested for the estimation of acetylene are absorption in ammoniacal cuprous chloride[10] or in a paste composed of cuprous chloride and aqueous caustic soda.[11] However, since these substances also absorb olefins, diolefins, and carbon monoxide to some extent, their application is limited.

Oxygen is estimated by absorption in an alkaline solution of pyrogallol[12] or by yellow phosphorus.[13] Brückner and Bloch[14] compared the activity of pyrogallol (1,2,3-trihydroxybenzene), sodium hyposulphite and 1,2,4-trihydroxybenzene. They report that the absorption rate and the total amount of oxygen absorbed in pyrogallol is greatest when potassium hydroxide is mixed with the phenol in the proportion of 1.5:1 by weight. However, if the gases under analysis contain more than 25 per cent of oxygen, the pyrogallol decomposes and carbon monoxide is produced. This difficulty is said to be eliminated by the use of 1,2,4-trihydroxybenzene (1,2,4-benzenetriol) and potassium hydroxide in the ratio 1:5.5 by weight. The rate of absorption in alkaline sodium hyposulphite, it is stated, is much slower than with either of the above reagents. One mole of the hyposulphite takes up only 0.94 moles of oxygen as compared with 1.5 moles for either of the trihydroxybenzenes, measured over the same period of time. According to Schmid[15] the amount of uncombined oxygen in a gas may be determined in the following manner. An alkaline solution of potassium iodide containing a small proportion of sodium potassium tartrate (Rochelle's Salt) is mixed with aqueous manganese chloride. The gases are then held in contact with this mixture for a period of 2 minutes to effect the absorption of oxygen. At the end of the contact time, the solution is acidified to liberate unreacted iodine, and the latter titrated with sodium thiosulphate.

Unsaturated hydrocarbons may be absorbed in a dilute solution of bromine in fuming sulphuric acid or in concentrated sulphuric acid containing 1 per cent of silver sulphate. Other procedures for the determination of the total quantity of unsaturated hydrocarbon gases involve use of an aqueous solution of bromine to minimize corrosion of mercury when the latter is employed as the confining liquid. Also fuming sulphuric acid is a rapid absorbent for all olefins but has the disadvantage that it slowly absorbs paraffin hydrocarbons.

Carbon monoxide may be estimated by conducting gases containing this substance through a vertical tube in which it is mixed with an atomized stream of aqueous ammoniacal cuprous chloride. The amount of carbon monoxide absorbed is determined by measuring the conductivity of the absorbing liquid before and after absorption.[16] Brückner and Gröbner[17] point out that a neutral solution of 125 g. of cuprous chloride and 265 g. of ammonium chloride in a liter of solution is best adapted for the determination of carbon monoxide. The rate of absorption of carbon monoxide in an acid solution of cuprous chloride is said to be increased by the addition of hydrochloric acid, but at the same time the total absorptive capacity decreases. According to these investigators, ammoniacal cuprous chloride shows a very low rate of absorption and absorbing capacity, irrespective of the amount of ammonium hydroxide present. Silver oxide has also been suggested as a reagent for the estimation of carbon monoxide.[18]

Hydrogen sulphide may be absorbed in pellets of manganese dioxide which have been soaked in phosphoric acid and from which all gas has been removed.[19] In one test with 90 cc. of illuminating gas 75 per cent of the hydrogen sulphide was absorbed by the reagent in 20 minutes, after which the remainder was taken up in a solution of copper sulphate acidified with sulphuric acid. Among the other reagents suggested are lead acetate[20] and iodine solutions.[21] When a gas sample is found to contain both hydrogen sulphide and sulphur dioxide, a comparison method is recommended.[22] Hydrogen sulphide and sulphur dioxide reduce iodine according to the equations:

$$\begin{aligned} H_2S + 2I &\longrightarrow 2HI + S \\ SO_2 + 2I + 2H_2O &\longrightarrow 2HI + H_2SO_4 \end{aligned}$$

The quantity of iodine reduced by conducting the gas under analysis directly through 0.1N iodine is compared with that reduced when the same volume of gas is passed through 40 per cent potassium hydroxide (to absorb hydrogen sulphide and sulphur dioxide) and then through 0.1N iodine in potassium iodide. In this manner other constituents which would also reduce iodine (e.g., olefins) can be quantitatively estimated. The difference in the number of cc. of iodine reduced in the two cases represents the volume of hydrogen sulphide and sulphur dioxide present. Roelen and Feisst[23] advocate the use of alkaline hydrogen peroxide for determining the sulphur compounds in gases. The gases are forced into a solution of 200 cc. of 0.5N sodium hydroxide and 100 cc. of 5 per cent hydrogen peroxide at the rate of 100 liters per hour.[24] A turbine stirrer rotating at 4000 r.p.m. is said to maintain an efficient contact between the gas and the liquid at this rate. The sulphur compounds are converted into sulphates and may be determined gravimetrically. One reported disadvantage of this method is the fact that any sulphur present in the form of thiophene is not absorbed.

Helium is usually determined as the residue after adsorption in charcoal of the gases in a specimen. In one form of apparatus a vertical gas burette is connected through the lower end to a mercury pump. At the upper end a glass tube leads to a bulb containing charcoal which is cooled with liquid air. (See Fig. 274.) From this bulb the gases flow to the lower end of the burette. In the tube between the burette and bulb there is a Plueckner tube[25] consisting of two platinum wires contained in a capillary tube through which a spark is passed. The procedure consists of forcing the gas to be tested into the burette after the latter has been evacuated. The volume of gas is measured and passed over the charcoal to adsorb all the constituents except helium. The latter is then introduced into the burette and its volume measured.[26] Anderson[27] suggests an analogous process in which natural gas is first conducted through a condenser tube which is surrounded by liquid air.

In this manner water vapor, carbon dioxide, ethane and heavier hydrocarbon gases are condensed. The remaining gas is then pumped through two connected tubes containing activated coconut charcoal. On issuing from the second of these tubes the gases are examined spectroscopically, and if helium alone is present the volume is measured.

Blacet and MacDonald[28] have described a method for the microanalysis of gases containing hydrogen, carbon monoxide, hydrogen chloride and ammonia. The samples were confined in a burette over mercury and the volume of the constituents estimated before and after inserting the proper absorbent. (See Fig. 275.) A bead made by fusing together cupric oxide and potassium hydroxide on a platinum loop was said to be satisfactory for absorbing hydrogen completely in 15 minutes. Carbon monoxide may be absorbed by the same reagent, hydrogen chloride by a solution of concentrated potassium hydroxide in a sintered glass bead, and ammonia by a moistened phosphorus pentoxide bead or by concentrated sulphuric acid in sintered glass.[29] A bath of molten lead was employed to maintain a constant temperature.

ANALYSIS BY COMBUSTION AND EXPLOSION

When the absorbable constituents of natural and cracking gases have been removed, paraffin hydrocarbons, hydrogen and nitrogen remain, together with some carbon monoxide and organic sulphur compounds. In the analysis of coal gas in which the paraffin is mainly methane, determination of this gas is a relatively easy matter. Hydrogen is oxidized to water by copper oxide at 280°C. or by palladium sponge at 100°C. and the residual methane-nitrogen mixture is then exploded with excess of air.[30] However, with natural or cracking gas in which a number of homologous gaseous paraffins are present the above method is not directly applicable. It therefore becomes necessary to effect some fractionation of the constituents. A number of procedures for effecting such fractionation on an analytical scale will be discussed below. When the gas contains sulphur and carbon monoxide, these must also be determined. The sulphur content is ascertained first, the percentage of carbon monoxide being estimated together with hydrogen.

Organic sulphur may be determined by oxidizing the sulphur compounds to sulphates. In this procedure, the gas is heated with an excess of air, converting the sulphur compounds to sulphur dioxide. The latter is then absorbed in a sodium carbonate solution and is oxidized to sulphate by air according to the equations.[31]

$$\begin{aligned} SO_2 + Na_2CO_3 &\longrightarrow Na_2SO_3 + CO_2 \\ 2Na_2SO_3 + O_2 &\longrightarrow 2Na_2SO_4 \end{aligned}$$

Afterwards the excess alkali is titrated with standard hydrochloric acid solution, employing methyl orange as an indicator. If the sodium carbonate solution is made up by dissolving 3.306 g. of the anhydrous salt in a liter of solution, 1 cc. of the solution will be equivalent to 0.001 g. of sulphur. Then if the acid solution contains 2.275 g. of hydrochloric acid per liter, 10 cc. of this solution will neutralize 10 cc. of the sodium carbonate solution. Using solutions of these strengths, the concentration of sulphur in the gas in grams per 100 cubic feet is given by the expression

$$\text{Sulphur concentration} = 1.543\,\frac{\text{cc. } Na_2CO_3 \text{ taken} - \text{cc. HCl used}}{\text{cu. ft. of gas burned}}$$

Carbon Monoxide. In addition to other well known methods, the gas may be determined by oxidation to carbon dioxide. According to Meyer and Slooff[32] iodine pentoxide will convert the monoxide to the dioxide at 120-130°C. Methane is said to be inert to the oxidizing agent at this temperature. To separate the iodine (liberated during oxidation) and methane the temperature is reduced to —80°C. at which iodine is condensed. The temperature is further reduced by liquid air to condense the carbon dioxide and part of the methane. Since methane has a considerable vapor pressure at this temperature (of liquid air) it may be removed by a mercury pump. The carbon dioxide may then be vaporized and measured in a gas burette. To obtain the sum of carbon monoxide and methane, a second sample is burned to carbon dioxide and measured as indicated above. Meyer and Slooff state that hydrogen reacts to some extent with the iodine pentoxide but does not influence the results within the limits of experimental error.

Hydrogen usually is estimated by oxidizing this gas to water and measuring the reduction in volume (or, in pressure at constant volume). A method developed for this purpose consists in passing the gas mixture very slowly over fresh copper oxide maintained at a temperature of 280°C. in a silica tube.[33] Treatment is continued until no further diminution in volume takes place, which usually requires about 30 minutes. This method is reported to be satisfactory when methane is the main gaseous paraffin constituent. Ethane and its higher homologues are said to be oxidized slowly in this manner, and, therefore, in the presence of large proportions of these substances, the method is unreliable. Among the other procedures suggested for the determination of hydrogen are oxidation in the presence of palladium in the form of a "sponge," wire, or colloidal solution.[34]

DETERMINATION OF THE PARAFFIN HYDROCARBONS BY OXIDATION

Methane may be determined by a slow combustion method employing cupric oxide.[34a] Walker and Christensen[35] state that a serious objection to this procedure is the danger of explosion. They suggest the use of a catalyst prepared by evaporation and subsequent thermal decomposition of 1.2 g. of cupric nitrate trihydrate and 14 g. of cobalt nitrate hexahydrate on 40 g. of unglazed porcelain particles. When the gas under analysis is passed over the catalyst mentioned above and subsequently over cupric oxide at a rate of 20-25 cc. per minute, the efficiency of the catalyst is reported to be at a maximum at a temperature of 500-550°C. as indicated in Fig. 276. The optimum ratio of oxygen to methane was said to be 3:1 by volume. In the procedure a single furnace with a compound combustion tube or two furnaces employing separate combustion tubes with a manifold may be used. Platinum has also been recommended as a catalyst for the oxidation of methane at temperatures in the range 800-900°C.[36] Kobe and Brookbank[37] report that platinized silica gel has no effect upon the oxidation of methane at 350°C., but that some carbon dioxide can be obtained at 370°C., though the reaction is not complete even at the latter temperature. The absorption of carbon dioxide by the catalyst is so small (1.35 cc. per gram at 0°C. and 740 mm. pressure) that it does not interfere with the results. A method for microanalysis of gases containing methane has been developed.[38] The apparatus consists of a length of glass tubing in which a platinum wire has been fused, so that the latter extends 1 cm. beyond the end of the glass tubing. This is placed in the gas holder and the reservoir below this holder filled with mercury. The gas containing the methane is then burned by heating the wire to a reddish orange glow.

temperature reached 400°C. the reaction was still incomplete. Shepherd and Branham[39] conducted an investigation on the combustion of ethane to determine the amount of that hydrocarbon present in a sample of natural gas. The alkane was analyzed by a slow combustion method with excess oxygen and with a hot platinum spiral as contact agent. The contraction in volume of the gas upon burning, the volume of carbon dioxide produced and of oxygen consumed were measured. The volumes involved in the ideal gas reaction

$$\begin{array}{lcl} C_2H_6 + 3.5\ O_2 & \longrightarrow & 2CO_2 + 2.5 \text{ vol. contraction} \\ 1 \text{ vol.} + 3.5 \text{ vol.} & \longrightarrow & 2 \text{ vol.} + 2.5 \text{ vol. contraction} \end{array}$$

were said to be at variance with the observed volumes. An empirical equation which more nearly represents the results obtained was written as:

$$\begin{array}{lcl} C_2H_6 + 3.513\ O_2 & \longrightarrow & 1.994CO_2 + 2.52 \text{ vol. contraction} \\ 1 \text{ vol.} + 3.513 \text{ vol.} & \longrightarrow & 1.994 \text{ vol.} + 2.52 \text{ vol.} \end{array}$$

This would indicate that the contraction and oxygen consumed were higher than the ideal values and the carbon dioxide produced was lower. The sources of error which would influence the results include the solubility of carbon dioxide in the water in the apparatus and in the water formed in combustion, the solubility of the dioxide in the rubber parts of the apparatus, and losses of ethane by its solubility in the stopcock lubricant. To compare these results with those obtained from explosion methods, a series of analyses of pure ethane were made by explosion with: (1) commercial oxygen containing a small proportion (0.76 per cent) of nitrogen;

(2) pure electrolytic oxygen and (3) air.[40] Relatively large differences were found between the various groups of analyses, with no group giving results which would correspond to the ideal equations. Some of the errors which might have caused these differences were examined. In the experiments in which commercial oxygen was used it was reported that oxides of nitrogen were formed in the explosion and influenced the values for the volumes of contraction and of oxygen consumed. In each of the three cases incomplete combustion was proved by finding carbon monoxide in the products of burning, amounting to 0.3 per cent of the sample. Slight additional contraction was also noticed when, after removing the carbon dioxide, the remaining gas was passed over the heated platinum spiral of the combustion pipette. This was said to be either unburned ethane from the original sample or ethane dissolved in the rubber and lubricant of the apparatus. The conclusion was reached that this procedure is not particularly efficient since results showing the presence of 5 to 15 per cent of methane were secured from a gas which was known to be pure ethane.

FIG. 277A.—Sketch of Vaporizing Tube Shown in Fig. 277.

Complete combustion of gas mixtures containing appreciable proportions of higher paraffins by passage over heated cupric oxide has been stated to be satisfactory. This method, although not quite quantitative, is said to furnish results of sufficient accuracy. Any carbon dioxide which is absorbed by the cupric oxide may be removed by treatment of the hot oxide with a stream of air. When the hydrocarbons have been completely oxidized to carbon dioxide and water, the resulting gas mixture may be removed from the cupric oxide by evacuation and the carbon dioxide and oxygen determined by absorption. To minimize the danger of explosions in the combustion method for analysis of propane, Bruun and Faulconer[41] have proposed controlled evaporation. The hydrocarbon is burned in a mixture of nitrogen and oxygen, as shown in Fig. 277. The samples to be analyzed are first cooled and enclosed in sealed Pyrex glass tubes drawn out into a fine capillary opening at one end. Each tube is then placed in a vaporizing tube (Fig. 277A) which has been cooled below the boiling point of propane (—42.2°C.). The tip of the sample tube is broken, and the rate of evaporation of the sample controlled by slowly lowering the cooling medium. If a residue remains in the tube after evaporation, it may be removed by heating the tube with an electric furnace.

Koetschau and Schmitt[42] have described a combustion apparatus which is reported to be sensitive to gasoline concentrations of 0.1 per cent in air. It consists of a Wheatstone bridge with four wires which are in thermal equilibrium when surrounded by air. The mixture under analysis is burned by passage over one pair of wires which are electrically heated, while air is heated over the other pair in a similar manner. Changes in the resistance of the first pair of wires, due to the extra heat derived from the combustion, cause deflection of two galvanometer needles, one on a scale graduated to show the percentage (to as low as 1 per cent) of gasoline in the air, the other on a scale graduated in divisions which enable the detection of concentrations of 0.1 per cent.

ANALYSIS BY CONDENSATION

Absorption and combustion analyses are in themselves quite inadequate for a complete analysis of natural gases or of complex mixtures such as gases from cracking plants and hydrogenation units. A physical separation is necessary to completely determine the proportion of each of the alkanes, olefins and diolefins present. In general the mixed hydrocarbons are subjected to low-temperature condensation followed by fractional distillation.

The analytical separation of any individual hydrocarbon by fractionation from a mixture of homologous hydrocarbons becomes more difficult as the series ascends.[43] As the number of carbon atoms becomes greater, the vapor pressures of the individual hydrocarbons, hence their boiling points, tend to approach one another more closely. The difficulties associated with the fundamental analysis of hydrocarbon mixtures are thus quite obvious. Fortunately, there are only about 20 known gaseous hydrocarbons whose boiling points at atmospheric pressure are within a range of 170°C., and very few mixtures would probably contain them all.

Tropsch and Mattox[44] reported that a mixture of hydrocarbons condensed from a gas sample at the temperature of liquid nitrogen may be distilled into composite fractions containing 2 or 3 and 3 or 4 carbon atoms per molecule. The separation is effected without the use of a fractionating column by simple evaporation at controlled low temperatures (from —195° to —105°C.) and correspondingly low pressures (1 mm. of mercury) and by fractional condensation in a series of glass bulbs each cooled to the proper temperature by liquid nitrogen and by aluminum blocks containing this substance. In the procedure advantage is taken of the high vapor pressure ratios existing between the constituents at low temperatures. This difference of vapor pressure causes the rates of evaporation of each fraction to vary widely from that of every other fraction and makes possible the selection of temperatures such that the less volatile components possess in each case a negligible vapor pressure and the more volatile components relatively high vapor pressures. Since these condensation temperatures are fairly constant for the removal of each fraction, the separation may be accomplished by varying the pressure rather than the temperature. Another advantage reported to result from the use of low pressures is the fact that the actual amount of the vapor phase over the liquid phase is quite small at low pressures, so that a negligible percentage of the vapor phase remains above the liquid at the completion of each condensation, an important consideration where limited amounts of gas are at hand.

Hydrogen, carbon monoxide, oxygen, nitrogen and methane are removed from the condensable hydrocarbons at the temperature of liquid nitrogen (—195°C.) by reducing the pressure to 0.1 mm., and the percentage of these constituents may be determined by absorption and combustion, as described previously. Acetylene is separated from the gas before condensation. The vapor pressure of ethane remains so low at the temperature of liquid nitrogen that none of it is removed with the methane distillate. Pentane and heavier hydrocarbons present in the gas mixture are quantitatively condensed from the butanes at a temperature of —105°C. and 1 mm. pressure. Fractionation of the remaining hydrocarbons into two composite fractions is made at 1 mm. pressure and at temperatures of —135 to —140°C. and at —195°C. The components of these fractions are listed in Table 209.

TABLE 209.—*Components of Hydrocarbon Mixtures Obtained by Fractional Condensation*

Fraction	Temperature of Condensation °C.	Constituents

the olefins by concentrated sulphuric acid activated by nickel and silver sulphates. The density of the olefins may be calculated from the change in the density of the fraction upon removal of these substances. The volume of each hydrocarbon and the per cent by volume of each hydrocarbon in the original sample may then be estimated from the known density of the two olefins, the known density of the two paraffins, and the volumes of olefins and paraffins.

The third fraction contains hydrocarbons which are liquids at temperatures below 20°C. This portion is reported as gasoline, either as grams per liter of gas, as volume per cent or as gallons of gasoline per 1000 cubic feet of gas, each of the calculations being made from the volume and density of the vaporized fraction. The density determinations of Tropsch and Mattox were made with a Stock electromagnetic gas-density balance which operates according to the principle of determining specific gravity by measuring the buoyancy produced on a small hollow quartz ball (fastened to a scale beam) by the influence of the surrounding gases. This is illustrated in Fig. 278. One of the reported advantages of this method is that relatively small samples, 500 cc. or slightly less, may be completely analyzed.

FIG. 280.—Relation of Specific Gravity to Molecular Weight for Hydrocarbons *n*-Pentane to *n*-Octane. (H. Tropsch and W. J. Mattox)

A somewhat similar procedure is suggested by the same investigators[45] for determination of the gasoline (i.e., easily liquefied vapors) content of gases. The sample is condensed at the temperature of liquid nitrogen and at atmospheric pressure. By reducing the pressure to 0.1 mm. of mercury, methane and other difficultly condensable gases (especially dissolved nitrogen) are removed. The condensate is then fractionated at −105°C., a temperature at which the hydrocarbons above C_4 are liquid. The hydrocarbons C_5 and higher are then vaporized into a known volume where the pressure and temperature can be measured. These gasoline vapors are condensed by liquid nitrogen in a bulb which may be removed from the apparatus and weighed. The apparatus is illustrated in Fig. 279. From the weight of the gasoline and the pressure it exerts when vaporized in a known volume at a definite temperature, the average molecular weight of the sample is calculated. By means of a curve relating the molecular weights to the specific gravities of the pure hydrocarbons (see Fig. 280) the specific gravity of the gasoline is read. With the weight of the gasoline from a known volume of gas and the specific gravity of the gasoline, the gallons of gasoline per 1000 cubic feet of gas at 60°F. (15°C.) and 30 inches (760 mm.) of mercury may be calculated from the formula:

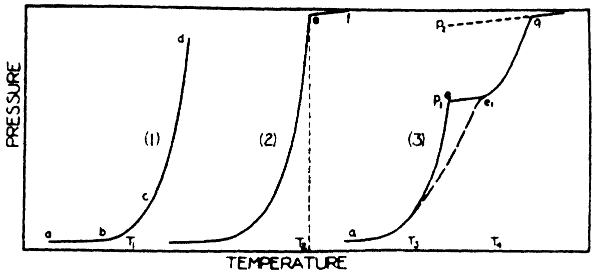
---

[45] H. Tropsch and W. J. Mattox, *Ind. Eng. Chem., Anal. Ed.*, 1934, 6, 405; *Brit. Chem. Abs.* B, 1935, 54; *Chem. Abs.*, 1935, 29, 327.

$$G = \frac{19.39 \times g(t_1 + 273)}{S \times P \times V}$$

where G = gallons of gasoline per thousand cubic feet of wet gas at 60°F. (15°C.) and 30 inches (760 mm.) of mercury, g = weight of gasoline, grams, t_1 = temperature of gas sample, °C., S = specific gravity of gasoline at 20°C., P = pressure of gas sample, and V = volume (liters) of the gas sample.

Sebastian and Howard[46] suggest a method for the microanalysis of gaseous mixtures based upon the characteristic form of vapor pressure-temperature curves.



Courtesy Industrial and Engineering Chemistry

FIG. 281.—Idealized Pressure-Temperature Curves for Gases. (J. J. S. Sebastian and H. C. Howard)

If p, the pressure, is plotted against the absolute temperature, a curve of the form shown in Fig. 281, Curve 1, is obtained. From this curve it may be seen that for small values of pressure the latter increases only slightly even when there is a considerable change in the temperature. As the temperature increases over a longer range there is a rapid rise in the pressure, which is followed by a sharp, almost linear rise. The period of rapid change in pressure is designated by the investigators as the initial vaporization temperature. If a closed system of one component is studied, the relation of a vapor phase in equilibrium with its solid or liquid phase, is given by this curve. If, however, the system is sufficiently large so that the condensed phase ultimately disappears, the curve takes the shape indicated in Curve 2. If T_2 represents the absolute temperature at which the condensed phase disappears, the curve beyond this point represents the expansion of the vapor with rise in temperature the value of which is comparatively small.

If two substances form separate phases in the condensed states, and if the initial vaporization temperatures are sufficiently far apart, the more volatile compound will be relatively completely evaporated from the condensed phase before the vapor pressure of the second becomes appreciable. By plotting the pressure against the absolute temperature a curve of the form of Curve 3 (Fig. 281) will be obtained from which the quantitative composition may be determined. The initial vaporization temperatures T_3 and T_4 are characteristics of the components and represent the qualitative composition. The ratio of p_1 to p_2 gives the fraction by volume of the more volatile component present in the mixture, from which the quantitative composition may be calculated.

The procedure consists in condensing 1 ml. (cc.) of the gas under analysis in a bulb cooled by liquid nitrogen. (See Fig. 282.) The apparatus is evacuated to 10^{-5} mm. and the temperature of the liquid nitrogen slowly raised, about 0.4° to 0.6°C. per minute. The temperature and pressure are read at frequent intervals and plotted against each other. From these data the composition of the gases may be estimated. One of the limitations of the system is said to be in the fact that it has not been possible to determine saturated and unsaturated hydrocarbons of the same number of carbon atoms when both are present in the gas specimen.

An explanation for the rather widely separated boiling points of methane and ethane, when compared with each other and with the remaining members of this homologous series, has been offered by Cox.[47] The reasons given for believing that methane and ethane are not homologous with other hydrocarbons of the paraffin series with regard to boiling point are:

1. Methane contains a carbon-hydrogen bond of unique strength not found elsewhere in the series.
2. Ethane contains a carbon-carbon bond also of unique strength not found elsewhere in the series.
3. Propane contains no bonds that are not duplicated in the higher members of the series.

If methane and ethane are treated as separate problem entities, it is stated that the remainder of the normal paraffin series can be related by the equation:

$$\log B = 1.07575 + 0.949128 \log m - 0.101 \log^2 m$$

where B is the normal boiling point in °K. (assuming 0°C.=273.16°K.), m is the approximate molecular weight, and the logarithms are to base 10.

LOW-TEMPERATURE FRACTIONATION METHODS

Among the outstanding advances in the analysis of complex hydrocarbon mixtures by physical methods is the development of efficient fractionating columns capable of being used for the precise fractional distillation of small quantities of hydrocarbon liquids at temperatures down to the boiling point of liquid nitrogen. The types of apparatus which have been recommended for this procedure include those of Podbielniak, Frey and Yant, Davis, Schaufelberger, MacGillivray and Rosen and Robertson.[48] The Podbielniak apparatus consists essentially of a vacuum-jacketed fractionating column designed for high efficiency at reflux temperatures below atmospheric, together with an accessory apparatus for introducing gas or liquid samples into the column and for temperature and volume measurement. Refrigerants such as liquid air, liquid carbon dioxide, brine, water and compressed air are employed to give the proper reflux ratio. In the column suggested by Frey and Yant controlled reflux was obtained by regulated heat withdrawal from the uppermost 10 cm. of a 50 cm. fractionating column. The effect was accomplished by cooling with liquid air through a 1 mm. annular space filled with hydrogen, whose pressure could be regulated. In this manner the rate of cooling could be controlled. The column described by Davis consists of glass tubing bent into a low pitch spiral of 30 to 40 turns. An immersion-type electrical heating device and a cooled receiver for condensation of the distillate vapors are employed. Schaufelberger advocates a reflux chamber separate from the fractionating column in an apparatus similar to that of Podbielniak. According to MacGillivray, a variable-pressure hydrogen buffer will efficiently control the reflux ratio when the refrigerant is liquid nitrogen. The latter substance will not form explosive mixtures with hydrocarbons in the event of a leak as will liquid air. Rosen and Robertson point out that a column is not necessary in routine analysis of ternary mixtures but that the pressure and temperature of a vaporizing mixture may be plotted and the composition estimated by comparison with a master graph.[49]

Lang[50] has described a modification of the Podbielniak apparatus which is reported to be efficient for the analysis of gas mixtures containing nitrogen, oxygen, hydrogen, carbon monoxide, carbon dioxide, methane, ethylene, ethane, propene and propane. The sample was introduced into a distilling flask, and any components not condensable at the temperature of liquid air and atmospheric pressure were pumped off into a 100 cc. burette.

For receiving the fractions from the distillation a special 100 cc. burette was used. The burette, instead of being fitted with a compensator tube, was connected at the bottom through a side tube to an auxiliary leveling tube of the same base as the burette and located parallel to the burette. This leveling tube was enclosed in a water jacket. At the top the auxiliary leveling tube extended considerably above the gas burette and was open to the atmosphere, serving as a manometer to indicate the pressure of the gas in the burette with respect to the atmosphere. At the bottom the gas burette was also connected through a stopcock to a leveling tube. During the distillation a three-way stopcock at the top of the gas burette connected the latter to the distillation column. In this manner the auxiliary leveling tube in connection with the burette served as a manometer to show the distillation pressure. The rate of distillation can be controlled by opening the stopcock at the lower end of the gas burette. By regulating the reflux in the column the mercury in the gas burette and in the auxiliary leveling tube could be kept at the same level.

When a fraction was to be separated, or when the burette was full, the three-way stopcock at the top of the burette was closed, the distillation interrupted by cooling and the volume read. The three-way stopcock was then opened to a mercury filled gas-sampling tube and the distillate transferred.

The cut made at the ethylene boiling point range of the distillation curve (—115°C.) was said to contain hydrogen, carbon monoxide, nitrogen, methane and ethylene. This fraction was further analyzed by absorption and combustion, as described previously. The next cut was made between the ethane (—98°C.) and propene (—61°C.) boiling point ranges. The difference in boiling points should be sufficient to give a sharp break in the distillation curve, but in some cases it was necessary to add ethane to the sample to secure a clear ethane fraction which could further be separated into an ethylene-ethane portion and one of ethane-propene. The third cut contained the remainder of propene, propane and any higher homologues.

Eucken and Knick[51] proposed a method for the microanalytical separation of low-boiling hydrocarbons, based upon adsorption of their vapors by activated charcoal. The latter is contained in one arm of a U-tube, which is cooled to —103°C. by liquid ethylene. The tube is then slowly raised into an electrically heated furnace at 250°C. The gases which are evolved are continuously withdrawn from the other arm of the tube by a mercury pump and conducted to a collecting vessel. The pressures in the U-tube and collecting vessel, respectively, are read at frequent intervals and recorded as functions of the time of desorption. The gases are removed from the tube successively, the point at which each constituent is completely removed being marked by a minimum value of pressure in the tube. The proportions of constituents are then determined from the values for the pressure in the collecting vessel which correspond to the minimum values in the tube. The method has been reported as successful in the quantitative determination of a mixture of methane, ethylene, ethane and propane.

AZEOTROPIC MIXTURES IN LOW-TEMPERATURE FRACTIONATION

The development of precision methods for the analysis of complex hydrocarbon gases obviously is fraught with considerable difficulty. This is true especially in the separation of ethylene from ethane by low-temperature fractional distillation methods.[52] In some instances further fractionation of this cut very often resulted in the isolation of an azeotropic mixture of acetylene and ethane of minimum boiling point. According to McMillan, a mixture containing 70 per cent of ethane and 30 per cent of acetylene distilled at —94.5°C. until 73.5 per cent had come over, at which point the temperature broke sharply to —83.3°C., and the remainder of the ethane distilled at that temperature. With 70 per cent acetylene and 30 per cent ethane, a distillate amounting to 50.2 per cent of the mixture came over at —94.5°C., at which point the fractionating column froze solid with acetylene. When analyzed by catalytic hydrogenation of the acetylene over a reduced nickel catalyst, each of the azeotropic mixtures boiling at —94.5°C. gave 40.8 per cent of acetylene and 59.2 per cent of ethane. Additional determinations on five other samples gave a boiling point range of —94.5 ± 0.1°C. and a composition range of: acetylene, 40.75 ± 0.25 per cent; ethane, 59.25 ± 0.25 per cent for the azeotropic mixture. These results offer an explanation for the presence of acetylene as shown by tests with various reagents even though no acetylene had been observed on fractional distillation of the sample. It is also reported to explain at least in part the appearance of so-called "carbon dioxide plugs" which develop from time to time in distillation apparatus although the gases have been previously scrubbed with fresh caustic. The white solid which separates in such cases is usually not carbon dioxide but acetylene, which can be identified by Lebeau's reagent (mentioned in the section in this chapter on absorption).

Azeotropic mixtures have been employed in some cases to effect the separation of otherwise difficultly divided hydrocarbon portions. For example, the practical fractionation of a mixture of hydrocarbons having 4 carbon atoms to the molecule into a butene cut and a butane cut by distillation is said to be very difficult.[53] This is due to the small boiling point range (see Table 210).

TABLE 210.—*Boiling Points of Butanes and Butenes.*

	B.P., °C.		B.P., °C.
Isobutane	−12.4	*n*-Butane	−0.6
Isobutene	− 6.7	2-Butene (*trans.*)	1.0
1-Butene	− 6.7	2-Butene (*cis*)	3.7

Moreover, the order of the hydrocarbons with respect to boiling point necessitates obtaining 4 fractions instead of 2.

Separation is reported to be more readily effected by distillation in the presence of sulphur dioxide which forms azeotropic mixtures with the minimum boiling points at atmospheric pressure shown in Table 211.

TABLE 211.—*Boiling Points of Azeotropes of Butanes and Butenes.*

Azeotrope	B.P., °C.	Azeotrope	B.P., °C.
Isobutane	−27	Isobutene	−17
n-Butane	−21	2-Butene (mixture of *cis* and *trans* forms)	−16
1-Butene	−18		

The order of the azeotropes with respect to boiling point differs from that of the hydrocarbons themselves for both the butane azeotropes are said to have boiling points lower than any butene azeotropes. If sulphur dioxide is added to a mixture of 4 carbon hydrocarbons in amounts equivalent to the azeotropes of the butanes present which lies between 59 and 62 per cent for cracked or cracking gas, and if the resulting mixture is then fractionally distilled, the butanes can be separated from the butenes. In this manner azeotropic mixtures of the butanes are formed, boiling between −27° and −21°C., while the butenes do not form azeotropes and boil between−6.7° and 3.7°C. Thus there is a difference of about 14°C. between the highest boiling paraffin azeotrope and the lowest boiling olefin.

DETERMINATION OF UNSATURATED HYDROCARBONS IN GAS MIXTURES

The quantitative estimation of unsaturated hydrocarbons in gas mixtures likewise seems to be a matter of some difficulty, and can only be effected in few cases without some method of fractionation. Attention has been given to the analysis of olefin mixtures by absorption in various concentrations of sulphuric acid, with or without the addition of metallic salts. With sulphuric acid of appropriate concentration it is possible to effect an analytical separation of ethylene from its higher homologues because ethylene is absorbed with most difficulty by sulphuric acid. However, the rates of absorption of propene and the two straight-chain butenes approach one another so closely that any analytical separation of them by this acid seems to be rather impracticable.

Determination of the total amount of unsaturated hydrocarbons in a gas mixture is identical with the problem of complete absorption of the ethylene which takes place only after a relatively long time, while the other unsaturated hydrocarbon gases require contact periods of much shorter duration. Bromine and fuming sulphuric acid are the reagents usually employed for this purpose.[54] Of the two, bromine water is reported to be more efficient, especially if the operation is carried out in a darkened pipette. Fuming sulphuric acid rapidly absorbs all unsaturated hydrocarbons, including ethylene, but simultaneously paraffin hydrocarbons also.

ABSORPTION OF OLEFINS BY SULPHURIC ACID OF VARIOUS CONCENTRATIONS

A number of methods have been proposed for the preferential absorption of various individual olefins by treatment with sulphuric acid of different concentrations. It has been suggested that 87 per cent sulphuric acid activated by silver and nickel sulphates be used for ethylene, 83 to 84 per cent acid for propene and 63 to 64 per cent acid for isobutene.[55]

Tropsch and Mattox[56] have described a method for estimating ethylene, propene and butene in cracked refinery gases. Propene and butene are estimated by a method which consists essentially in determining the molecular weight of the original gas sample (dry and free of carbon dioxide and hydrogen sulphide) and also after the removal of propene and butene by 87 per cent sulphuric acid. These values are obtained with a Stock electromagnetic gas balance mentioned previously in this chapter. From the change in the molecular weight of the gas on the removal of propene and butene by the acid and the volume per cent of propene and butene removed, the molecular weight of these olefins is calculated and also the volume per cent of propene and of butene in the original mixture is computed. Ethylene is determined (after removal of other olefins) by absorption in a mixture comprising 1 to 15 per cent of concentrated sulphuric acid saturated with nickel sulphate at 20°C. and concentrated sulphuric acid containing 0.6 per cent of silver sulphate. The apparatus consists of a gas burette connected to a Stock electromagnetic gas balance and to two absorption bulbs (Fig. 284). One-half of a 200 cc. sample is used for the molecular weight determination, while the other 100 cc. is treated to remove the propene and butene simultaneously.

When ethylene is to be employed in the preparation of ethyl alcohol, it may be necessary to remove the higher olefins. According to Sakmin and Michnovska[57] the propene content of a gas mixture may be determined by absorption in sulphuric acid. In this method 80 cc. of the gas under analysis is forced into a gas burette and treated with 30 cc. of 87 per cent sulphuric acid. If less than 10 per cent of propene is present, the absorption is said to be complete in 10 minutes.

ANALYSIS OF GASEOUS UNSATURATED HYDROCARBONS BY BROMINATION

Two general methods for the addition of bromine to olefins and diolefins have been reported. The first consists of mixing the gaseous hydrocarbon mixture with bromine water, the second of treating the gas under analysis with potassium bromate, potassium bromide and sulphuric acid.[58] The three latter substances evolve bromine slowly according to the mechanism:

FIG. 284.—Apparatus for Determination of Propene and Butene in Gaseous Mixtures. (H. Tropsch and W. J. Mattox)

The first method, that is, determination of olefins by the use of bromine water, is said to be attended with some difficulties.[59] Among these are:

1. If the gas contains a high percentage of unsaturated hydrocarbon gases, it is difficult on account of the slow diffusion of bromine vapors to get the latter sufficiently mixed with the gas to react completely with the olefins present.
2. When mercury is used as the confining liquid in the gas burette it is necessary to avoid contact of bromine fumes with this metal.
3. When the percentage of paraffins in the sample is high, the solubility of these gases in bromine water is sufficiently great to introduce serious errors in the determination of small amounts of olefins.
4. When excess bromine vapors are removed by absorption in sodium or potassium hydroxide after reaction with olefins, the evolution of oxygen by decomposition of the hypobromite formed must be avoided.

The investigator reported that these difficulties can be overcome to a large degree by employing a solution saturated with both sodium chloride and bromine instead of bromine water as the absorbing medium. In this manner the absorption of paraffins was said to be reduced to a negligible amount. A pipette containing 25 per cent caustic soda was attached to the bulb containing the absorbing solution. The caustic soda was placed in the apparatus to remove bromine fumes. The procedure consisted of bubbling the gas through the bromine solution, if the concentration of olefins was high. If low, part of the gas was bubbled through the solution and the remainder conducted into the excess bromine fumes, the object being to expose only a small quantity of the gas to the solution and at the same time to insure excess bromine in the gas. The brominated gas is then drawn through the caustic soda pipette by suction and forced through a tube to a caustic potash solution. In this way the excess bromine vapors are removed. To minimize the error caused by evolution of oxygen in the caustic soda pipette, fresh reagent was added frequently.

Winbladh[60] suggests that cracked petroleum gases be treated with bromine water at —20 to —30°C. to form dibromides and tetrabromides, respectively, of the monolefins and diolefins present. The bromination products are collected in ice-cooled 10 per cent potassium bromide solution and distilled under 15 mm. pressure to separate the dibromides of ethylene, propene and butene from those derived from higher olefins. The residue, which contains the diolefin tetrabromides (as well as the higher dibromides), is agitated with hot ethyl alcohol. On cooling the mixture to 0°C. crystals of butadiene tetrabromide are said to be obtained. One portion of the distillate on shaking with a solution of disodium thioglycolate forms crystals of ethylenebisthioglycolic acid which may be dried and weighed. A second portion of this distillate is again fractionated into two cuts, the first boiling below 44°C. under 15 mm., the second boiling between 44 and 55°C. under 15 mm. The fractions were then treated with alcoholic disodium thioglycolate and caustic soda. The olefins other than ethylene may then be estimated by adding potassium bromate, potassium bromide and sulphuric acid to the two cuts from the last distillation. Excess bromine is replaced by iodine from potassium iodide and the iodine titrated with sodium thiosulphate. The process is reported to be tedious, four days being required for a complete determination. In addition, the error in estimating the olefins other than ethylene is said to be as high as 5.5 per cent.

Mulliken and Wakeman[61] point out that the bromide-bromate titration may be applied to the determination of mono- and diolefins. In their procedure they recommend that the calculated amount[62] of standardized bromide-bromate solution be placed in a glass-stoppered flask and mixed with 0.5 cc. of the hydrocarbon mixture. Then 15 cc. of 10 per cent sulphuric acid are incorporated. The bottle is stoppered and shaken until the bromine color vanishes. Instead of disappearing, should a visible bromine color still remain after two minutes of shaking, 5 cc. of 15 per cent potassium iodide are added and the liberated iodine titrated with 0.2N thiosulphate solution. If the color of the bromine disappears additional aqueous bromide-bromate is added until a yellow color persists in the solution. Potassium iodide is incorporated and the liberated iodine titrated with sodium thiosulphate.

Special Methods of Analysis of Unsaturated Gases

For the determination of acetylene in gases which contain high percentages of that substance, Novotny[63] suggested that the mixture be treated with silver

[60] R. Winbladh, *Ing. Vetenskaps, Akad. Handl.*, 1936, **138**; *Chem. Abs.*, 1936, **30**, 3746; *Brit. Chem. Abs.* **B**, 1936, 732.

[62] To the observed boiling point of the hydrocarbon mixture, 25°C. was added. The amount of bromide-bromate solution theoretically necessary to titrate an olefin boiling at such a temperature was calculated. This quantity of bromide-bromate solution minus 2 cc. is employed. Hence, less than the amount theoretically necessary for the hydrocarbon at hand was always used at the beginning.

[63] D. F. Novotny, *Collection Czechoslov. Chem. Communications*, 1935, 7, 84; *Brit. Chem. Abs.* **B**, 1935, 394; *Chem. Abs.*, 1935, **29**, 3940.

nitrate to form a precipitate of the silver nitrate complex of silver acetylide ($C_2Ag_2NO_3$). The latter is filtered off and the excess silver nitrate titrated with 0.1N ammonium thiocyanate or determined gravimetrically as silver chloride.

A method for the estimation of gaseous olefins by catalytic hydrogenation has been proposed.[64] It requires that a measured volume of hydrogen be mixed with a known quantity of olefin-containing gas and the mixture passed over an appropriate catalyst at 20°C. and 1 atmosphere pressure. The resulting contraction in volume is a direct measure of the amount of olefin present.

FIG. 286.—Gas Burette and Absorption Tube Employed in Determination of Butadiene in Gas Mixtures. (H. Tropsch and W. J. Mattox)

According to Dillon, Young and Lucas[65] mixtures of the three normal butenes can be analyzed by means of the densities of their dibromides and the reaction rate of these latter compounds with potassium iodide. The method depends on the fact that each of the three butenes is quantitatively converted to the dibromide by treatment with bromine, and each of the dibromides has a different second-order reaction rate with potassium iodide in methanol at 75°C. A combination of the reaction rate with the density is sufficient for the analysis of any mixture of the three dibromides, and from this the content of the three butenes can be computed. To investigate the possibility of the dibromide mixture undergoing isomerization during the reaction with potassium iodide, the stability of these substances was tested by distillation at atmospheric pressure.[66] A sample of 111.5 g. of dibromobutane, containing the three types and having n_D^{25} 1.5118, reaction rate constant (with potassium iodide) 0.0600 and $d_4^{25} = 1.7835$, was reported to distil between 159-165°C., leaving no high boiling residue. The distillate was found to have n_D^{25} 1.5118, reaction rate constant 0.0598 and d_4^{25} 1.7828. The absence of change in the reaction rate constant was said to show that no isomerization had occurred. Traces of decomposition products due to the loss of hydrogen bromide were reported as the cause of the slight change in density, but it was stated that a distillation at reduced pressure would restore the density to its previous value.

FIG. 287.—Apparatus for Continuous Determination of Helium in Natural Gas by Thermal-Conductivity Measurement. (A. S. Smith)

Tropsch and Mattox[67] suggest the use of maleic anhydride for the estimation of butadiene. The reaction between these two substances is said to be rapid at 100°C., which would seem to point out an advantage in using the molten anhydride. The apparatus consisted of a gas burette in connection with an absorption tube. (See Fig. 286.) Boiling water was circulated about the absorption pipette to maintain the temperature at 100°C. The gas was forced through the absorbent twice and the diminution in volume noted. It is stated that the anhydride does not absorb olefins or acetylene if the concentration of the latter is less than 40 per cent.

The use of a Wheatstone bridge for the determination of helium and argon in natural gas is proposed by Gerling.[68] The gases were heated by two wires of the bridge and the change in thermal conductivity noted. The pressure, if it is above 40 mm., is said to have no effect upon the thermal conductivity or resistance. The apparatus was originally calibrated with pure gases and is reported to be sensitive to 0.3 per cent of helium in a sample. To remove the hydrocarbons which are present, measured volumes of natural gas and oxygen are mixed and the hydrocarbons separated by combustion.[69] In the procedure natural gas was led through an inlet flow meter at one l. per hour at 0°C. and 760 mm., while oxygen entered at 1.685 l. per hour under the same conditions. The two were admixed and conducted at a space velocity of 0.27 to 0.69 cc. per hour per cc. of reaction space through a quartz combustion tube. The latter contained cobalt oxide at 800°C. As the gases leave the combustion chamber, condensed water vapor is removed in a water trap, and carbon dioxide by scrubbing with caustic soda and ascarite.[69a] The gas, in which the concentration of helium has been increased, is then analyzed by thermal-conductivity measurement.

Chapter 50

Analysis of Petroleum Distillates

Petroleum oils consist of extremely complex mixtures of hydrocarbon material together with smaller amounts of organic compounds containing, e.g., nitrogen and sulphur, and still smaller proportions of inorganic substances (See Chapter 1). During the course of refining operations, it is usual to remove almost all of the non-hydrocarbon substances since these are considered present as impurities which are held to be injurious in the commercial products. It is convenient to treat the methods used in the quantitative evaluation of these different substances first and then proceed to a consideration of the measurement and significance of physical characteristics of petroleum fractions.[1]

HYDROCARBON ANALYSIS

As has been pointed out in Chapter 1, the petroleums obtained from different portions of the world differ in their composition to a considerable extent. One of the principal differences is in the type of the predominant hydrocarbons. Thus, the oils from Baku and Grozny contain a high proportion of naphthenic constituents whereas oils from Pennsylvania are very largely paraffinic. On the other hand, aromatic hydrocarbons seem to be the characteristic components of petroleums from Borneo. Olefins apparently do not occur to any appreciable extent in crude petroleum, although they may form as much as 60 per cent of the gasoline resulting from vapor phase cracking.[2] Because of the influence of these various types of hydrocarbons on the uses and properties of petroleum and its fractions, it is of importance to differentiate between them and to estimate their relative proportions in any given distillate. The problems presented in these distinctions are rendered more difficult by the complexity of the petroleum itself and the variation in reactivity of the different members of any homologous series.

Polyakin[3] has described a method by which he determines quantitatively the alkenes, aromatics, six- and five-carbon-ring-naphthenes and paraffins in gasoline.

His procedure is to pass the vapors from a weighed sample (0.1 to 0.5 g.) through a series of absorption chambers and combustion tubes in which is maintained an atmosphere of nitrogen. Unsaturates are absorbed by a solution of mercuric acetate, and after drying the residual vapors the aromatic hydrocarbons are removed by sulphuric acid containing silver nitrate. The naphthenes with six-membered rings are dehydrogenated to aromatic hydrocarbons by passage at 300°C. over platinized asbestos. The five-carbon-ring-naphthenes and the paraffins are unaffected by this treatment. The aromatics are absorbed in sulphuric acid, after which the penta-naphthenes and paraffins are adsorbed on activated carbon. The hydrogen from the dehydrogenation on platinized asbestos is burned at 300°C. in a tube containing cupric oxide, and the water absorbed by phosphorus pentoxide.

In addition to methods which depend upon chemical analysis, analyses may be computed from data obtained in simple tests. For example, if v is the volume of unsaturated and aromatic hydrocarbons in a distillate, T the 50 per cent point (°F.) of the residue after treatment with sulphuric acid and d the specific gravity of the distilled residue, the percentage of paraffinic and naphthenic hydrocarbons has been calculated from formulas given by Minter.[4]

$$\text{Paraffin }\% = \frac{\left(1 - \frac{v}{100}\right)(0.7126 + 0.000244T - d)}{(0.0591 + 0.000016T)100}$$

$$\text{Naphthene }\% = \frac{\left(1 - \frac{v}{100}\right)(1 - 0.7126 + 0.000244T - d)}{(0.0591 + 0.000016T)100}$$

Tilicheev and Masina[5] have reported a method for the calculation of aromatic and unsaturated compounds in a gasoline which depends upon the determination of the aniline point before and after treatment with Kattwinkel's reagent (phosphoric and sulphuric acids) and also after treatment with 98 per cent sulphuric acid. Further, the proportion of aromatic compounds may be determined by reacting unsaturates with bromine and separating the portion containing aromatics by distillation. In the latter distillate the aromatics are determined by sulphonation. Using sulphuric acid of specific gravity 1.84 to remove aromatics from 50 cc. of a gas oil, a somewhat similar procedure for the analysis of gas oils has been described by van Dijk.[6] The naphthene content is subsequently calculated by using the specific refraction methods described later in this chapter.

The estimation of aliphatic hydrocarbons in aromatic hydrocarbons, such as commercial benzene, has been outlined by Goettsch.[6a] One volume of the hydrocarbon and 5 volumes of 95 per cent ethanol are mixed. To 30 cc. of this mixture in a 50 cc. bottle, water is added from a burette until separation of the hydrocarbon just takes place. By reference to tables (based on determinations with known mixtures), it is then possible to read off the per cent of aromatics in the original hydrocarbon mixture.

A micromethod for the estimation of the hydrocarbons in cracked gasoline has been proposed by Bespolov and Generalov.[7] This procedure is very similar, in the separate tests used, to the method of Polyakin[8] previously described. The essential differences are that unsaturated compounds are absorbed in bromine dissolved in acetic acid rather than in mercuric acetate solution, and subsequent operations are not carried out in a continuous manner.

THE USE OF ULTRAVIOLET LIGHT IN CLASSIFICATION OF HYDROCARBONS

The use of ultraviolet light in the artificial aging of gasoline and other petroleum fractions has been discussed in Chapter 40. The characteristic fluorescence of different classes of hydrocarbons under the influence of light from either a mercury or iron arc light has been recommended as a possible method for distinguishing between various hydrocarbons and waxes. Generally the fluorescence has not been sufficiently characteristic to permit of the identification of the several compounds studied in mixtures.[9] According to Balada[10] the fluorescence of naphthenic oils is blue, of asphaltic oils brown and of paraffin-base oils a light milky-yellow. He suggested that it would be possible to follow the change from naphthenic (blue fluorescence) to asphaltic (brown fluorescence) substances which takes place during oxidation of insulating or lubricating oils up to an asphalt content of about 0.40 per cent. This method is said to be capable of a reasonable degree of accuracy when applied to oils from the same source.

ESTIMATION OF ALKENES

The quantitative estimation of alkenes (ethylenic hydrocarbons) has been effected by several reactions which are typical of this class of compounds.[11] Among the more usual methods may be mentioned absorption in sulphuric acid,[12] halogenation, reaction with mercuric salts or with other reagents such as ozone, sulphur monochloride[13] and antimony trichloride.[14]

Absorption of alkenes in sulphuric acid is complicated by the fact that acid strong enough to remove polymers of diolefins (which may be present due to the action of the acid) will also extract some of the aromatic hydrocarbons.[15] It is suggested that the proportion of aromatic and olefinic hydrocarbons may be determined collectively by absorption in 98.3 per cent sulphuric acid and individually by absorption of the olefins in a 6 per cent aqueous mercuric acetate solution.[16]

Milas and McAlevy[17] observed that furoperacid[18] may be used for the estimation of unsaturated hydrocarbons but that quantitative results were not obtained in all cases. This is also the case with other peracids, such as perbenzoic and percamphoric acids.[19]

Halogenation of unsaturated linkages has been proposed also. For example, the slow liberation of bromine (in the presence of olefinic hydrocarbons) from an aqueous solution of potassium bromate and bromide by sulphuric acid is said to be a useful method. Under these conditions there is little tendency for substitution of hydrogen (in the hydrocarbon) by the halogen to occur. This procedure, which was developed by Francis,[20] has been modified somewhat by Mulliken and Wakeman.[21] The amount of bromide-bromate solution to be added is 2 cc. less than the amount necessary for the alkene which would boil 25°C. higher than the sample under investigation. The procedure is given:

The calculated amount of standardized bromide-bromate solution is run into a 118 cc. (4-oz.) glass-stoppered bottle, 0.5 cc. of hydrocarbon is then added, and finally 15 cc. of 10 per cent sulphuric acid. The bottle is stoppered quickly and shaken well until the bromine color vanishes and does not reappear when agitation is temporarily stopped. If, instead of disappearing, a visible bromine color still remains after 2 minutes' shaking, 5 cc. of 15 per cent potassium iodide are added and the liberated iodine is titrated with $0.2N$ thiosulphate solution. If, on the other hand, the color disappears, more bromide-bromate solution is added, 1 cc. at a time, until a visible yellow color finally persists after 2 minutes of shaking. Titration is then completed.

This procedure was found to be suitable for determination of the degree of unsaturation in alkenes, cycloalkenes and alkadienes, but not for alkynes and only doubtfully in terpenes. Titration of cyclopentadiene by the bromide-bromate method gives inaccurate results, largely due to formation of a peroxide of the hydrocarbon.[22]

Other methods by which halogenation may be effected involve the use of iodine, bromine, iodine chloride, or a solution of iodine bromide in glacial acetic acid.[23] Some difficulty is frequently experienced in using these reagents with dark-colored petroleum oil because of masking of the color of the iodine or bromine.

Hugel and Krassilchik[24] have applied the thiocyanogen number (which has found some application in the study of fats and oils) to the estimation of the unsaturation of hydrocarbons. The reagent in the present instance consists of a solu-

tion of thiocyanogen in an organic solvent such as acetic acid. This may be prepared either from lead thiocyanate and bromine or by the addition of bromine to a solution of sodium thiocyanate in glacial acetic acid.[25] Thiocyanate numbers have been used in the study of the composition of cracked gasoline. The results indicated that there was some difference in the reaction between an olefin and thiocyanogen from that between an olefin and mercuric acetate.[26]

ESTIMATION OF UNSATURATION BY HYDROGENATION

Procedures for the estimation of unsaturation by addition of halogens or thiocyanogen have the serious disadvantage that combination is only quantitative in certain cases, such as with normal alkenes. Some diolefins, e.g., isoprene and 2,4-dimethylpentadiene-1,3, give bromine numbers which are approximately one-half of the theoretical value. De Kok, Waterman and van Westen[27] have described a method of hydrogenation of organic substances by which it is possible to determine the degree of unsaturation readily. Their procedure is to bring a weighed amount of substance and a measured volume of hydrogen in intimate contact with an oxygen-free palladium- or platinum-on-asbestos catalyst at about 200°C. After reaction, the excess hydrogen is pumped into a gas burette where the volume is measured. From the amount of gas thus united, the unsaturation of the compound may be calculated. Some of the results obtained by the hydrogenation method are compared with the corresponding values obtained by the bromine method of McIlhiney[28] as shown in Table 212.

TABLE 212.—*Hydrogenation of Unsaturated Compounds.*

Compound	Hydrogen Value. Per Cent of Theory	Bromine Value. Per Cent of Theory
Olefins		
Amylene	100.8	100.4
Hexene-1	101.1	99.9
Heptene-1	100.3	98.2
Octene-1	100.6	100.3
Decene	101.4	100.7
Hexadecene	99.6	99.9
Diolefins		
Isoprene	99.7	50.0
2,4-Dimethylpentadiene-1,3	101.4	42.8–48.6
2,5-Dimethylheptadiene	101.0	65.5–67.4
Cyclic Compounds		
Cyclohexene	100.3	99.8
α-Pinene	99.9	>100.
Styrene (Pd catalyst)	100.8	100.3
Styrene (Pt catalyst)	100.3	100.3
